Introduction

This is the Annotated Ada Reference Manual.

Other available Ada documents include:

- \{AI95-00387-01\} \{AI05-0245-1\} Ada 2012 Rationale. This gives an introduction to the changes and new features in Ada 2012, and explains the rationale behind them. Programmers should read this rationale before reading this Standard in depth. Rationales for Ada 83, Ada 95, and Ada 2005 are also available. Ada 95 Rationale. This Rationale for the Ada Programming Language — 1995 edition, which gives an introduction to the new features of Ada incorporated in the 1995 edition of this Standard, and explains the rationale behind them. Programmers unfamiliar with Ada 95 should read this first.

  **Discussion:** \{AI05-0245-1\} As of this writing (December 2012), only five chapters of the Ada 2012 Rationale have been published. Additional chapters are in development and should be published during 2013.

- \{AI95-00387-01\} \{AI05-0245-1\} Ada 2005 Rationale. This gives an introduction to the changes and new features in Ada 2005 (compared with the 1995 edition), and explains the rationale behind them. Programmers should read this rationale before reading this Standard in depth.

  **This paragraph was deleted.** Changes to Ada — 1987 to 1995. This document lists in detail the changes made to the 1987 edition of the standard.

Design Goals

\{AI95-00387-01\} Ada was originally designed with three overriding concerns: program reliability and maintenance, programming as a human activity, and efficiency. The 1995 revision to the language was designed to provide greater flexibility and extensibility, additional control over storage management and synchronization, and standardized packages oriented toward supporting important application areas, while at the same time retaining the original emphasis on reliability, maintainability, and efficiency. This third edition, amended version provides further flexibility and adds more standardized packages within the framework provided by the 1995 revision.

The need for languages that promote reliability and simplify maintenance is well established. Hence emphasis was placed on program readability over ease of writing. For example, the rules of the language require that program variables be explicitly declared and that their type be specified. Since the type of a variable is invariant, compilers can ensure that operations on variables are compatible with the properties intended for objects of the type. Furthermore, error-prone notations have been avoided, and the syntax of the language avoids the use of encoded forms in favor of more English-like constructs. Finally, the language offers support for separate compilation of program units in a way that facilitates program development and maintenance, and which provides the same degree of checking between units as within a unit.

Concern for the human programmer was also stressed during the design. Above all, an attempt was made to keep to a relatively small number of underlying concepts integrated in a consistent and systematic way.
while continuing to avoid the pitfalls of excessive involution. The design especially aims to provide language constructs that correspond intuitively to the normal expectations of users.

Like many other human activities, the development of programs is becoming ever more decentralized and distributed. Consequently, the ability to assemble a program from independently produced software components continues to be a central idea in the design. The concepts of packages, of private types, and of generic units are directly related to this idea, which has ramifications in many other aspects of the language. An allied concern is the maintenance of programs to match changing requirements; type extension and the hierarchical library enable a program to be modified while minimizing disturbance to existing tested and trusted components.

No language can avoid the problem of efficiency. Languages that require over-elaborate compilers, or that lead to the inefficient use of storage or execution time, force these inefficiencies on all machines and on all programs. Every construct of the language was examined in the light of present implementation techniques. Any proposed construct whose implementation was unclear or that required excessive machine resources was rejected.

**Language Summary**

An Ada program is composed of one or more program units. Program units may be subprograms (which define executable algorithms), packages (which define collections of entities), task units (which define concurrent computations), protected units (which define operations for the coordinated sharing of data between tasks), or generic units (which define parameterized forms of packages and subprograms). Each program unit normally consists of two parts: a specification, containing the information that must be visible to other units, and a body, containing the implementation details, which need not be visible to other units. Most program units can be compiled separately.

This distinction of the specification and body, and the ability to compile units separately, allows a program to be designed, written, and tested as a set of largely independent software components.

An Ada program will normally make use of a library of program units of general utility. The language provides means whereby individual organizations can construct their own libraries. All libraries are structured in a hierarchical manner; this enables the logical decomposition of a subsystem into individual components. The text of a separately compiled program unit must name the library units it requires.

**Program Units**

A subprogram is the basic unit for expressing an algorithm. There are two kinds of subprograms: procedures and functions. A procedure is the means of invoking a series of actions. For example, it may read data, update variables, or produce some output. It may have parameters, to provide a controlled means of passing information between the procedure and the point of call. A function is the means of invoking the computation of a value. It is similar to a procedure, but in addition will return a result.

A package is the basic unit for defining a collection of logically related entities. For example, a package can be used to define a set of type declarations and associated operations. Portions of a package can be hidden from the user, thus allowing access only to the logical properties expressed by the package specification.

Subprogram and package units may be compiled separately and arranged in hierarchies of parent and child units giving fine control over visibility of the logical properties and their detailed implementation.

A task unit is the basic unit for defining a task whose sequence of actions may be executed concurrently with those of other tasks. Such tasks may be implemented on multicomputers, multiprocessors, or with interleaved execution on a single processor. A task unit may define either a single executing task or a task type permitting the creation of any number of similar tasks.
A protected unit is the basic unit for defining protected operations for the coordinated use of data shared between tasks. Simple mutual exclusion is provided automatically, and more elaborate sharing protocols can be defined. A protected operation can either be a subprogram or an entry. A protected entry specifies a Boolean expression (an entry barrier) that must be True before the body of the entry is executed. A protected unit may define a single protected object or a protected type permitting the creation of several similar objects.

**Declarations and Statements**

The body of a program unit generally contains two parts: a declarative part, which defines the logical entities to be used in the program unit, and a sequence of statements, which defines the execution of the program unit.

The declarative part associates names with declared entities. For example, a name may denote a type, a constant, a variable, or an exception. A declarative part also introduces the names and parameters of other nested subprograms, packages, task units, protected units, and generic units to be used in the program unit.

The sequence of statements describes a sequence of actions that are to be performed. The statements are executed in succession (unless a transfer of control causes execution to continue from another place).

An assignment statement changes the value of a variable. A procedure call invokes execution of a procedure after associating any actual parameters provided at the call with the corresponding formal parameters.

Case statements and if statements allow the selection of an enclosed sequence of statements based on the value of an expression or on the value of a condition.

The loop statement provides the basic iterative mechanism in the language. A loop statement specifies that a sequence of statements is to be executed repeatedly as directed by an iteration scheme, or until an exit statement is encountered.

A block statement comprises a sequence of statements preceded by the declaration of local entities used by the statements.

Certain statements are associated with concurrent execution. A delay statement delays the execution of a task for a specified duration or until a specified time. An entry call statement is written as a procedure call statement; it requests an operation on a task or on a protected object, blocking the caller until the operation can be performed. A called task may accept an entry call by executing a corresponding accept statement, which specifies the actions then to be performed as part of the rendezvous with the calling task. An entry call on a protected object is processed when the corresponding entry barrier evaluates to true, whereupon the body of the entry is executed. The requeue statement permits the provision of a service as a number of related activities with preference control. One form of the select statement allows a selective wait for one of several alternative rendezvous. Other forms of the select statement allow conditional or timed entry calls and the asynchronous transfer of control in response to some triggering event.

Execution of a program unit may encounter error situations in which normal program execution cannot continue. For example, an arithmetic computation may exceed the maximum allowed value of a number, or an attempt may be made to access an array component by using an incorrect index value. To deal with such error situations, the statements of a program unit can be textually followed by exception handlers that specify the actions to be taken when the error situation arises. Exceptions can be raised explicitly by a raise statement.
Data Types

Every object in the language has a type, which characterizes a set of values and a set of applicable operations. The main classes of types are elementary types (comprising enumeration, numeric, and access types) and composite types (including array and record types).

An enumeration type defines an ordered set of distinct enumeration literals, for example a list of states or an alphabet of characters. The enumeration types Boolean, Character, and Wide_Character, and Wide_Wide_Character are predefined.

Numeric types provide a means of performing exact or approximate numerical computations. Exact computations use integer types, which denote sets of consecutive integers. Approximate computations use either fixed point types, with absolute bounds on the error, or floating point types, with relative bounds on the error. The numeric types Integer, Float, and Duration are predefined.

Composite types allow definitions of structured objects with related components. The composite types in the language include arrays and records. An array is an object with indexed components of the same type. A record is an object with named components of possibly different types. Task and protected types are also forms of composite types. The array types String, and Wide_String, and Wide_Wide_String are predefined.

Record, task, and protected types may have special components called discriminants which parameterize the type. Variant record structures that depend on the values of discriminants can be defined within a record type.

Access types allow the construction of linked data structures. A value of an access type represents a reference to an object declared as aliased or to an object created by the evaluation of an allocator. Several variables of an access type may designate the same object, and components of one object may designate the same or other objects. Both the elements in such linked data structures and their relation to other elements can be altered during program execution. Access types also permit references to subprograms to be stored, passed as parameters, and ultimately dereferenced as part of an indirect call.

Private types permit restricted views of a type. A private type can be defined in a package so that only the logically necessary properties are made visible to the users of the type. The full structural details that are externally irrelevant are then only available within the package and any child units.

From any type a new type may be defined by derivation. A type, together with its derivatives (both direct and indirect) form a derivation class. Class-wide operations may be defined that accept as a parameter an operand of any type in a derivation class. For record and private types, the derivatives may be extensions of the parent type. Types that support these object-oriented capabilities of class-wide operations and type extension must be tagged, so that the specific type of an operand within a derivation class can be identified at run time. When an operation of a tagged type is applied to an operand whose specific type is not known until run time, implicit dispatching is performed based on the tag of the operand.

Interface types provide abstract models from which other interfaces and types may be composed and derived. This provides a reliable form of multiple inheritance. Interface types may also be implemented by task types and protected types thereby enabling concurrent programming and inheritance to be merged.

The concept of a type is further refined by the concept of a subtype, whereby a user can constrain the set of allowed values of a type. Subtypes can be used to define subranges of scalar types, arrays with a limited set of index values, and records and private types with particular discriminant values.
Other Facilities

Aspect clauses can be used to specify the mapping between types and features of an underlying machine. For example, the user can specify that objects of a given type must be represented with a given number of bits, or that the components of a record are to be represented using a given storage layout. Other features allow the controlled use of low level, nonportable, or implementation-dependent aspects, including the direct insertion of machine code.

The predefined environment of the language provides for input-output and other capabilities by means of standard library packages. Input-output is supported for values of user-defined as well as of predefined types. Standard means of representing values in display form are also provided. Other standard library packages are defined in annexes of the standard to support systems with specialized requirements.

The predefined standard library packages provide facilities such as string manipulation, containers of various kinds (vectors, lists, maps, etc.), mathematical functions, random number generation, and access to the execution environment.

The specialized annexes define further predefined library packages and facilities with emphasis on areas such as real-time scheduling, interrupt handling, distributed systems, numerical computation, and high-integrity systems.

Finally, the language provides a powerful means of parameterization of program units, called generic program units. The generic parameters can be types and subprograms (as well as objects and packages) and so allow general algorithms and data structures to be defined that are applicable to all types of a given class.

Language Changes

Paragraphs 44 through 57 have been removed as they described differences from the first edition of Ada (Ada 83).

This amended International Standard updates the edition of 1995 which replaced the first edition of 1987. In this edition, the following major language changes were incorporated:

- Support for standard 8-bit and 16-bit characters was added. See clauses 2.1, 3.5.2, 3.6.3, A.1, A.3, and A.4.
- The type model was extended to include facilities for object-oriented programming with dynamic run-time polymorphism. See the discussions of classes, derived types, tagged types, record extensions, and private extensions in clauses 3.4, 3.9, and 7.3. Additional forms of generic formal parameters were allowed, as described in clauses 12.5.1 and 12.7 by 12.5.1, “Formal Private and Derived Types” and 12.7, “Formal Packages”.
- Access types were extended to allow an access value to designate a subprogram or an object declared by an object declaration (as opposed to just an object allocated on a heap object). See clause 3.10.
- Efficient data-oriented synchronization was provided by the introduction of via protected types. See clause 9.4, Section 9.
- The library structure was extended to allow library units to be organized into a hierarchy of parent and child units. See clause 10.1, Section 10.
- Additional support was added for interfacing to other languages. See Annex B.
- The Specialized Needs Annexes were added to provide specific support for certain application areas.
This International Standard replaces the second edition of 1995. It modifies the previous edition by making changes and additions that improve the capability of the language and the reliability of programs written in the language. This edition incorporates the changes from Amendment 1 (ISO/IEC 8652:1995:AMD 1:2007), which were designed to improve the portability of programs, interfacing to other languages, and both the object-oriented and real-time capabilities.

Significant changes originating in Amendment 1 with respect to the 1995 edition are incorporated:

- Support for program text is extended to cover the entire ISO/IEC 10646:2003 repertoire. Execution support now includes the 32-bit character set. See clauses 2.1, 3.5.2, 3.6.3, A.1, A.3, and A.4.
- The object-oriented model has been improved by the addition of an interface facility which provides multiple inheritance and additional flexibility for type extensions. See clauses 3.4, 3.9, and 7.3. An alternative notation for calling operations more akin to that used in other languages has also been added. See clause 4.1.3.
- Access types have been further extended to unify properties such as the ability to access constants and to exclude null values. See clause 3.10. Anonymous access types are now permitted more freely and anonymous access-to-subprogram types are introduced. See clauses 3.3, 3.6, 3.10, and 8.5.1.
- The control of structure and visibility has been enhanced to permit mutually dependent references between units and finer control over access from the private part of a package. See clauses 3.10.1 and 10.1.2. In addition, limited types have been made more useful by the provision of aggregates, constants, and constructor functions. See clauses 4.3, 6.5, and 7.5.
- The predefined environment has been extended to include additional time and calendar operations, improved string handling, a comprehensive container library, file and directory management, and access to environment variables. See clauses 9.6.1, A.4, A.16, A.17, and A.18.
- Two of the Specialized Needs Annexes have been considerably enhanced:
  - The Real-Time Systems Annex now includes the Ravenscar profile for high-integrity systems, further dispatching policies such as Round Robin and Earliest Deadline First, support for timing events, and support for control of CPU time utilization. See clauses D.2, D.13, D.14, and D.15.
  - The Numerics Annex now includes support for real and complex vectors and matrices as previously defined in ISO/IEC 13813:1997 plus further basic operations for linear algebra. See clause G.3.
- The overall reliability of the language has been enhanced by a number of improvements. These include new syntax which detects accidental overloading, as well as pragmas for making assertions and giving better control over the suppression of checks. See clauses 6.1, 11.4.2, and 11.5.
In addition, this third edition makes enhancements to address two important issues, namely, the particular problems of multiprocessor architectures, and the need to further increase the capabilities regarding assertions for correctness. It also makes additional changes and additions that improve the capability of the language and the reliability of programs written in the language.

The following significant changes with respect to the 1995 edition as amended by Amendment 1 are incorporated:

- New syntax (the aspect specification) is introduced to enable properties to be specified for various entities in a more structured manner than through pragmas. See subclause 13.1.1.
- The concept of assertions introduced in the 2005 edition is extended with the ability to specify preconditions and postconditions for subprograms, and invariants for private types. The concept of constraints in defining subtypes is supplemented with subtype predicates that enable subsets to be specified other than as simple ranges. These properties are all indicated using aspect specifications. See subclauses 3.2.4, 6.1.1, and 7.3.2.
- New forms of expressions are introduced. These are if expressions, case expressions, quantified expressions, and expression functions. As well as being useful for programming in general by avoiding the introduction of unnecessary assignments, they are especially valuable in conditions and invariants since they avoid the need to introduce auxiliary functions. See subclauses 4.5.7, 4.5.8, and 6.8. Membership tests are also made more flexible. See subclauses 4.4 and 4.5.2.
- A number of changes are made to subprogram parameters. Functions may now have parameters of all modes. In order to mitigate consequent (and indeed existing) problems of inadvertent order dependence, rules are introduced to reduce aliasing. A parameter may now be explicitly marked as aliased and the type of a parameter may be incomplete in certain circumstances. See subclauses 3.10.1, 6.1, and 6.4.1.
- The use of access types is now more flexible. The rules for accessibility and certain conversions are improved. See subclauses 3.10.2, 4.5.2, 4.6, and 8.6. Furthermore, better control of storage pools is provided. See subclause 13.11.4.
- The Real-Time Systems Annex now includes facilities for defining domains of processors and assigning tasks to them. Improvements are made to scheduling and budgeting facilities. See subclauses D.10.1, D.14, and D.16.
- A number of important improvements are made to the standard library. These include packages for conversions between strings and UTF encodings, and classification functions for wide and wide wide characters. Internationalization is catered for by a package giving locale information. See subclauses A.3, A.4.11, and A.19. The container library is extended to include bounded forms of the existing containers and new containers for indefinite objects, multiway trees, and queues. See subclause A.18.
- Finally, certain features are added primarily to ease the use of containers, such as the ability to iterate over all elements in a container without having to encode the iteration. These can also be used for iteration over arrays, and within quantified expressions. See subclauses 4.1.5, 4.1.6, 5.5.1, and 5.5.2.
Instructions for Comment Submission

Informal comments on this International Standard may be sent via e-mail to ada-comment@ada-auth.org. ada-comment@sw-eng.falls-church.va.us. If appropriate, the Project Editor will initiate the defect correction procedure.

Comments should use the following format:

- !topic Title summarizing comment
- !reference Ada 2012 2005 RM RM95 ss.ss(pp)
- !from Author Name yy-mm-dd
- !keywords keywords related to topic
- !discussion

where ss.ss is the section, clause or subclause number, pp is the paragraph number where applicable, and yy-mm-dd is the date the comment was sent. The date is optional, as is the !keywords line.

Multiple comments per e-mail message are acceptable. Please use a descriptive “Subject” in your e-mail message, and limit each message to a single comment.

When correcting typographical errors or making minor wording suggestions, please put the correction directly as the topic of the comment; use square brackets [ ] to indicate text to be omitted and curly braces { } to indicate text to be added, and provide enough context to make the nature of the suggestion self-evident or put additional information in the body of the comment, for example:

- !topic [c]{C}haracter
- !topic if{[}is meaning is not defined

Formal requests for interpretations and for reporting defects in this International Standard may be made in accordance with the ISO/IEC JTC 1 Directives and the ISO/IEC JTC 1/SC 22 policy for interpretations. National Bodies may submit a Defect Report to ISO/IEC JTC 1/SC 22 for resolution under the JTC 1 procedures. A response will be provided and, if appropriate, a Technical Corrigendum will be issued in accordance with the procedures.
Acknowledgements for the Ada 83 edition

Ada is the result of a collective effort to design a common language for programming large scale and real-time systems.

The common high order language program began in 1974. The requirements of the United States Department of Defense were formalized in a series of documents which were extensively reviewed by the Services, industrial organizations, universities, and foreign military departments. The Ada language was designed in accordance with the final (1978) form of these requirements, embodied in the Steelman specification.

The Ada design team was led by Jean D. Ichbiah and has included Bernd Krieg-Brueckner, Brian A. Wichmann, Henry F. Ledgard, Jean-Claude Heliard, Jean-Loup Gailly, Jean-Raymond Abrial, John G.P. Barnes, Mike Woodger, Olivier Roubine, Paul N. Hilfinger, and Robert Firth.

Two parallel efforts that were started in the second phase of this design had a deep influence on the language. One was the development of a formal definition using denotational semantics, with the participation of V. Donzeau-Gouge, G. Kahn, and B. Lang. The other was the design of a test translator with the participation of K. Ripken, P. Boullier, P. Cadiou, J. Holden, J.F. Huertas, R.G. Lange, and D.T. Cornhill. The entire effort benefitted from the dedicated assistance of Lyn Churchill and Marion Myers, and the effective technical support of B. Gravem, W.L. Heimerdinger, and P. Cleve. H.G. Schmitz served as program manager.

Over the five years spent on this project, several intense week-long design reviews were conducted, with the participation of P. Belmont, B. Brosol, P. Cohen, R. Dewar, A. Evans, G. Fisher, H. Harte, A.L. Hisgen, P. Knueven, M. Kronental, N. Lomuto, E. Ploudereder, G. Seegmueller, V. Stenning, D. Taffs, and also F. Belz, R. Converse, K. Correll, A.N. Habermann, J. Sammet, S. Squires, J. Teller, P. Wegner, and P.R. Wetherall.

These reviews and comments, the numerous evaluation reports received at the end of the first and second phase, the nine hundred language issue reports and test and evaluation reports received from fifteen different countries during the third phase of the project, the thousands of comments received during the ANSI Canvass, and the on-going work of the IFIP Working Group 2.4 on system implementation languages and that of the Purdue Europe LTPL-E committee, all had a substantial influence on the final definition of Ada.

The Military Departments and Agencies have provided a broad base of support including funding, extensive reviews, and countless individual contributions by the members of the High Order Language Working Group and other interested personnel. In particular, William A. Whitaker provided leadership for the program during the formative stages. David A. Fisher was responsible for the successful development and refinement of the language requirement documents that led to the Steelman specification.
The Ada 83 language definition was developed by Cii Honeywell Bull and later Alsys, and by Honeywell Systems and Research Center, under contract to the United States Department of Defense. William E. Carlson and later Larry E. Druffel served as the technical representatives of the United States Government and effectively coordinated the efforts of all participants in the Ada program.

Acknowledgements for the Ada 95 edition

This International Standard was prepared by the Ada 9X Mapping/Revision Team based at Intermetrics, Inc., which has included: W. Carlson, Program Manager; T. Taft, Technical Director; J. Barnes (consultant); B. Brosgol (consultant); R. Duff (Oak Tree Software); M. Edwards; C. Garrity; R. Hilliard; O. Pazy (consultant); D. Rosenfeld; L. Shafer; W. White; M. Woodger.

The following consultants to the Ada 9X Project contributed to the Specialized Needs Annexes: T. Baker (Real-Time/Systems Programming — SEI, FSU); K. Dritz (Numerics — Argonne National Laboratory); A. Gargaro (Computer Sciences); J. Goodenough (Real-Time/Systems Programming — SEI); J. McHugh (Secure Systems — consultant); B. Wichmann (Safety-Critical Systems — NPL: UK).

This work was regularly reviewed by the Ada 9X Distinguished Reviewers and the members of the Ada 9X Rapporteur Group (XRG): E. Ploedereder, Chairman of DRs and XRG (University of Stuttgart: Germany); B. Bardin (Hughes); J. Barnes (consultant: UK); B. Brett (DEC); B. Brosgol (consultant); R. Brukardt (RR Software); N. Cohen (IBM); R. Dewar (NYU); G. Dismukes (TeleSoft); A. Evans (consultant); A. Gargaro (Computer Sciences); M. Gerhardt (ESL); J. Goodenough (SEI); S. Heilbrunner (University of Salzburg: Austria); P. Hilfinger (UC/Berkeley); B. Källberg (CelsiusTech: Sweden); M. Kamrad II (Unisys); J. van Katwijk (Delft University of Technology: The Netherlands); V. Kaufman (Russia); P. Kruchten (Rational); R. Landwehr (CCI: Germany); C. Lester (Portsmouth Polytechnic: UK); L. Månsson (TELIA Research: Sweden); S. Michell (Multiprocessor Toolsmiths: Canada); M. Mills (US Air Force); D. Pogge (US Navy); K. Power (Boeing); O. Roubine (Verdix: France); A. Strohmeier (Swiss Fed Inst of Technology: Switzerland); W. Taylor (consultant: UK); J. Tokar (Tartan); E. Vasilescu (Grumman); J. Vladik (Prospeks s.r.o.: Czech Republic); S. Van Vlierberghe (OFFIS: Belgium).

Other valuable feedback influencing the revision process was provided by the Ada 9X Language Precision Team (Odyssey Research Associates), the Ada 9X User/Implementer Teams (AETECH, Tartan, TeleSoft), the Ada 9X Implementation Analysis Team (New York University) and the Ada community-at-large.

The Ada 9X Project was sponsored by the Ada Joint Program Office. Christine M. Anderson at the Air Force Phillips Laboratory (Kirtland AFB, NM) was the project manager.

Acknowledgements for the Corrigendum version

The editor [R. Brukardt (USA)] would like to thank the many people whose hard work and assistance has made this update revision possible.

Thanks go out to all of the members of the ISO/IEC JTC 1/SC 22/WG 9 Ada Rapporteur Group, whose work on creating and editing the wording corrections was critical to the entire process. Especially valuable contributions came from the chairman of the ARG, E. Ploedereder (Germany), who kept the process moving; J. Barnes (UK) and K. Ishihata (Japan), whose extremely detailed reviews kept the editor on his toes; G. Dismukes (USA), M. Kamrad (USA), P. Leroy (France), S. Michell (Canada), T. Taft (USA), J. Tokar (USA), and other members too numerous to mention.
Special thanks go to R. Duff (USA) for his explanations of the previous system of formatting of these documents during the tedious conversion to more modern formats. Special thanks also go to the convenor of ISO/IEC JTC 1/SC 22/WG 9, J. Moore (USA), without whose help and support the Corrigendum and this consolidated reference manual would not have been possible.

**Acknowledgements for the Amendment 1 version**

The editor [R. Brukardt (USA)] would like to thank the many people whose hard work and assistance has made this update revision possible.

Thanks go out to all of the members of the ISO/IEC JTC 1/SC 22/WG 9 Ada Rapporteur Group, whose work on creating and editing the wording corrections was critical to the entire process. Especially valuable contributions came from the chairman of the ARG, P. Leroy (France), who kept the process on schedule; J. Barnes (UK) whose careful reviews found many typographical errors; T. Taft (USA), who always seemed to have a suggestion when we were stuck, and who also was usually able to provide the valuable service of explaining why things were as they are; S. Baird (USA), who found many obscure problems with the proposals; and A. Burns (UK), who pushed many of the real-time proposals to completion. Other ARG members who contributed were: R. Dewar (USA), G. Dismukes (USA), R. Duff (USA), K. Ishihata (Japan), S. Michell (Canada), E. Ploedereder (Germany), J.P. Rosen (France), E. Schonberg (USA), J. Tokar (USA), and T. Vardanega (Italy).

Special thanks go to Ada-Europe and the Ada Resource Association, without whose help and support the Amendment and this consolidated reference manual would not have been possible. M. Heaney (USA) requires special thanks for his tireless work on the containers packages. Finally, special thanks go to the convenor of ISO/IEC JTC 1/SC 22/WG 9, J. Moore (USA), who guided the document through the standardization process.

**Acknowledgements for the Ada 2012 edition**

The editor [R. Brukardt (USA)] would like to thank the many people whose hard work and assistance has made this revision possible.

Thanks go out to all of the members of the ISO/IEC JTC 1/SC 22/WG 9 Ada Rapporteur Group, whose work on creating and editing the wording changes was critical to the entire process. Especially valuable contributions came from the chairman of the ARG, E. Schonberg (USA), who guided the work; T. Taft (USA), whose insights broke many logjams, both in design and wording; J. Barnes (UK) whose careful reviews uncovered many editorial errors; S. Baird (USA), who repeatedly found obscure interactions with the proposals that the rest of us missed. Other ARG members who substantially contributed were: A. Burns (UK), J. Cousins (UK), R. Dewar (USA), G. Dismukes (USA), R. Duff (USA), P. Leroy (France), B. Moore (Canada), E. Ploedereder (Germany), J.P. Rosen (France), B. Thomas (USA), and T. Vardanega (Italy).

Special thanks go to Ada-Europe and the Ada Resource Association, without whose help and support this third edition of the Ada Standard would not have been possible. A special mention has to go to A. Beneschan (USA) for his efforts in eliminating sloppiness in our wording. M. Heaney (USA) also deserves a mention for his efforts to improve the containers packages. Finally, special thanks go to the convenor of ISO/IEC JTC 1/SC 22/WG 9, J. Tokar (USA), who guided the document through the standardization process.
Changes

The International Standard is the same as this version of the Reference Manual, except:

• This list of Changes is not included in the International Standard.
• The “Acknowledgements” page is not included in the International Standard.
• The text in the running headers and footers on each page is slightly different in the International Standard.
• The title page(s) are different in the International Standard.
• This document is formatted for 8.5-by-11-inch paper, whereas the International Standard is formatted for A4 paper (210-by-297mm); thus, the page breaks are in different places.

77.1/3

• This paragraph was deleted. The “Foreword to this version of the Ada Reference Manual” clause is not included in the International Standard.

77.2/3

• The “Using this version of the Ada Reference Manual” subclause is not included in the International Standard.

77.3/3

• Paragraph numbers are not included in the International Standard.

Using this version of the Ada Reference Manual

This document has been revised with the corrections specified in Technical Corrigendum 1 (ISO/IEC 8652:1995/COR.1:2001) and Amendment 1 (ISO/IEC 8652/AMD.1:2007), along with changes specifically for this third edition. In addition, more additional annotations have been added and a variety of editorial errors have been corrected.

Changes to the original 8652:1995 can be identified by the version number /1 following the paragraph number. Paragraphs with a version number /1 were changed by Technical Corrigendum 1 or were editorial corrections at that time, while paragraphs with a version number /2 were changed by Amendment 1 or were more recent editorial corrections, and paragraphs with a version number /3 were changed by the third (2012) edition of the Standard or were still more recent editorial corrections. Paragraphs not so marked are unchanged by the third edition, Amendment 1, Technical Corrigendum 1, or editorial corrections. Paragraph numbers of unchanged paragraphs are the same as in the 1995 edition of the original Ada Reference Manual. Inserted text is indicated by underlining, and deleted text is indicated by strikethroughs. Some versions also use color to indicate the version of the change. Where paragraphs are inserted, the paragraph numbers are of the form pp.nn, where pp is the number of the preceding paragraph, and nn is an insertion number. For instance, the first paragraph inserted after paragraph 8 is numbered 8.1, the second paragraph inserted is numbered 8.2, and so on. Deleted paragraphs are indicated by the text This paragraph was deleted. Deleted paragraphs include empty paragraphs that were numbered in the 1995 edition of the original Ada Reference Manual. Similar markings and numbering are used for changes to annotations.

To be honest: The paragraph number is considered part of the paragraph; when a paragraph is moved to a different paragraph number, it is marked as changed even if the contents have not changed.
1 General

\[\textit{AI05-0299-1}\] Ada is a programming language designed to support the construction of long-lived, highly reliable software systems. The language includes facilities to define packages of related types, objects, and operations. The packages may be parameterized and the types may be extended to support the construction of libraries of reusable, adaptable software components. The operations may be implemented as subprograms using conventional sequential control structures, or as entries that include synchronization of concurrent threads of control as part of their invocation. The language treats modularity in the physical sense as well, with a facility to support separate compilation.

\[\textit{AI05-0269-1}, \textit{AI05-0299-1}\] The language includes a complete facility for the support of real-time, concurrent programming. Errors can be signaled as exceptions and handled explicitly. The language also covers systems programming; this requires precise control over the representation of data and access to system-dependent properties. Finally, a predefined environment of standard packages is provided, including facilities for, among others, input output, string manipulation, numeric elementary functions, and random number generation.

\textbf{Discussion:} This Annotated Ada Reference Manual (AARM) contains the entire text of the third edition of the Ada Reference Manual (the Ada 2012 RM with Amendment 1 (the Ada 2005 RM (RM95)), plus certain annotations. The annotations give a more in-depth analysis of the language. They describe the reason for each nonobvious rule, and point out interesting ramifications of the rules and interactions among the rules (interesting to language lawyers, that is). Differences between Ada 83, Ada 95, and Ada 2005, and Ada 2012 and Ada 95 are listed. (The text you are reading now is an annotation.)

The AARM stresses detailed correctness and uniformity over readability and understandability. We’re not trying to make the language “appear” simple here; on the contrary, we’re trying to expose hidden complexities, so we can more easily detect language bugs. The Ada 2012 RM, on the other hand, is intended to be a more readable document for programmers.

The annotations in the AARM are as follows:

- Text that is logically redundant is shown [in square brackets, like this]. Technically, such text could be written as a Note in the Ada 2012 RM (and the Ada 95 and 2005 RMs before it) since it is really a theorem that can be proven from the nonredundant rules of the language. We use the square brackets instead when it seems to make the Ada 2012 RM more readable.

- The rules of the language (and some AARM-only text) are categorized, and placed under certain subheadings that indicate the category. For example, the distinction between Name Resolution Rules and Legality Rules is particularly important, as explained in 8.6.

- Text under the following subheadings appears in both documents:
  - The unlabeled text at the beginning of each clause or subclause,
  - Syntax,
  - Name Resolution Rules,
  - Legality Rules,
  - Static Semantics,
  - Post-Compilation Rules,
  - Dynamic Semantics,
  - Bounded (Run-Time) Errors,
  - Erroneous Execution,
  - Implementation Requirements,
  - Documentation Requirements,
  - Metrics,
  - Implementation Permissions,
  - Implementation Advice,
  - NOTES,
1.1 Scope

This International Standard specifies the form and meaning of programs written in Ada. Its purpose is to promote the portability of Ada programs to a variety of computing data processing systems.

Ada is a programming language designed to support the construction of long-lived, highly reliable software systems. The language includes facilities to define packages of related types, objects, and operations. The packages may be parameterized and the types may be extended to support the construction of libraries of reusable, adaptable software components. The operations may be implemented
as subprograms using conventional sequential control structures, or as entries that include synchronization of concurrent threads of control as part of their invocation. Ada supports object-oriented programming by providing classes and interfaces, inheritance, polymorphism of variables and methods, and generic units. The language treats modularity in the physical sense as well, with a facility to support separate compilation.

The language provides rich support for real-time, concurrent programming, and includes facilities for multicore and multiprocessor programming. Errors can be signaled as exceptions and handled explicitly. The language also covers systems programming; this requires precise control over the representation of data and access to system-dependent properties.

Finally, a predefined environment of standard packages is provided, including facilities for, among others, input-output, string manipulation, numeric elementary functions, and random number generation, and definition and use of containers.

1.1 Extent

This International Standard specifies:

- The form of a program written in Ada;
- The effect of translating and executing such a program;
- The manner in which program units may be combined to form Ada programs;
- The language-defined library units that a conforming implementation is required to supply;
- The permissible variations within the standard, and the manner in which they are to be documented;
- Those violations of the standard that a conforming implementation is required to detect, and the effect of attempting to translate or execute a program containing such violations;
- Those violations of the standard that a conforming implementation is not required to detect.

This International Standard does not specify:

- The means whereby a program written in Ada is transformed into object code executable by a processor;
- The means whereby translation or execution of programs is invoked and the executing units are controlled;
- The size or speed of the object code, or the relative execution speed of different language constructs;
- The form or contents of any listings produced by implementations; in particular, the form or contents of error or warning messages;
- The effect of unspecified execution.
- The size of a program or program unit that will exceed the capacity of a particular conforming implementation.

1.1.2 Structure

This International Standard contains thirteen clauses, sections, fourteen annexes, and an index.

Discussion: What Ada 83 called a “chapter” and Ada 95 (and Ada 2005) called a “section” is called a “clause” in this Standard. Similarly, what Ada 83 called a “section” and Ada 95 (and Ada 2005) called a “clause” is
The core of the Ada language consists of:

- \{AI05-0299-1\} Clauses Sections 1 through 13
- Annex A, “Predefined Language Environment”
- Annex B, “Interface to Other Languages”

The following Specialized Needs Annexes define features that are needed by certain application areas:

- Annex E, “Distributed Systems”
- Annex G, “Numerics”
- Annex H, “High Integrity Systems”

The core language and the Specialized Needs Annexes are normative, except that the material in each of the items listed below is informative:

- Text under a NOTES or Examples heading.
- Each clause or subclause whose title starts with the word “Example” or “Examples”.

All implementations shall conform to the core language. In addition, an implementation may conform separately to one or more Specialized Needs Annexes.

The following Annexes are informative:

- Annex N, “Glossary”
- \{AI05-0262-1\} Annex Q, “Language-Defined Entities”

Discussion: The idea of the Specialized Needs Annexes is that implementations can choose to target certain application areas. For example, an implementation specifically targeted to embedded machines might support the application-specific features for Real-time Systems, but not the application-specific features for Information Systems. The Specialized Needs Annexes extend the core language only in ways that users, implementations, and standards bodies are allowed to extend the language; for example, via additional library units, attributes, representation items (see 13.1), pragmas, and constraints on semantic details that are left unspecified by the core language. Many implementations already provide much of the functionality defined by Specialized Needs Annexes; our goal is to increase uniformity among implementations by defining standard ways of providing the functionality.

\{AI05-00114-01\} We recommend that the certification validation procedures allow implementations to certify validate the core language, plus any set of the Specialized Needs Annexes. We recommend that implementations not be allowed to certify validate a portion of one of the Specialized Needs Annexes, although implementations can, of course, provide uncertified unvalidated support for such portions. We have designed the Specialized Needs Annexes assuming that this recommendation is followed. Thus, our decisions about what to include and what not to include in those annexes are based on the assumption that each annex is certified validated in an “all-or-nothing” manner.
An implementation may, of course, support extensions that are different from (but possibly related to) those defined by one of the Specialized Needs Annexes. We recommend that, where appropriate, implementations do this by adding library units that are children of existing language-defined library packages.

An implementation should not provide extensions that conflict with those defined in the Specialized Needs Annexes, in the following sense: Suppose an implementation supports a certain error-free program that uses only functionality defined in the core and in the Specialized Needs Annexes. The implementation should ensure that that program will still be error free in some possible full implementation of all of the Specialized Needs Annexes, and that the semantics of the program will not change. For example, an implementation should not provide a package with the same name as one defined in one of the Specialized Needs Annexes, but that behaves differently, even if that implementation does not claim conformance to that Annex.

Note that the Specialized Needs Annexes do not conflict with each other; it is the intent that a single implementation can conform to all of them.

{AI05-0299-1} Each section clause is divided into clauses and subclauses that have a common structure. Each section, clause, and subclause first introduces its subject. After the introductory text, text is labeled with the following headings:

Language Design Principles

These are not rules of the language, but guiding principles or goals used in defining the rules of the language. In some cases, the goal is only partially met; such cases are explained.

{AI05-0005-1} This is not part of the definition of the language, and does not appear in the Ada 2012 RM.

Syntax

Syntax rules (indented).

Name Resolution Rules

{AI05-0299-1} Compile-time rules that are used in name resolution, including overload resolution.

Discussion: These rules are observed at compile time. (We say “observed” rather than “checked,” because these rules are not individually checked. They are really just part of the Legality Rules in Clause Section 8 that require exactly one interpretation of each constituent of a complete context.) The only rules used in overload resolution are the Syntax Rules and the Name Resolution Rules.

When dealing with nonoverloadable declarations it sometimes makes no semantic difference whether a given rule is a Name Resolution Rule or a Legality Rule, and it is sometimes difficult to decide which it should be. We generally make a given rule a Name Resolution Rule only if it has to be. For example, “The name, if any, in a raise_statement shall be the name of an exception.” is under “Legality Rules.”

Legality Rules

Rules that are enforced at compile time. A construct is legal if it obeys all of the Legality Rules.

Discussion: These rules are not used in overload resolution.

Note that run-time errors are always attached to exceptions; for example, it is not “illegal” to divide by zero, it just raises an exception.

Static Semantics

A definition of the compile-time effect of each construct.

Discussion: The most important compile-time effects represent the effects on the symbol table associated with declarations (implicit or explicit). In addition, we use this heading as a bit of a grab bag for equivalences, package specifications, etc. For example, this is where we put statements like so-and-so is equivalent to such-and-such. (We ought to try to really mean it when we say such things!) Similarly, statements about magically-generated implicit declarations go here. These rules are generally written as statements of fact about the semantics, rather than as a you-shall-do-such-and-such sort of thing.

Post-Compilation Rules

Rules that are enforced before running a partition. A partition is legal if its compilation units are legal and it obeys all of the Post-Compilation Rules.
29.a Discussion: It is not specified exactly when these rules are checked, so long as they are checked for any given partition before that partition starts running. An implementation may choose to check some such rules at compile time, and reject compilation_units accordingly. Alternatively, an implementation may choose to check such rules when the partition is created (usually known as “link time”), or when the partition is mapped to a particular piece of hardware (but before the partition starts running).

Dynamic Semantics

30 A definition of the run-time effect of each construct.

30.a Discussion: This heading describes what happens at run time. Run-time checks, which raise exceptions upon failure, are described here. Each item that involves a run-time check is marked with the name of the check — these are the same check names that are used in a pragma Suppress. Principle: Every check should have a name, usable in a pragma Suppress.

Bounded (Run-Time) Errors

31 Situations that result in bounded (run-time) errors (see 1.1.5).

31.a Discussion: The “bounds” of each such error are described here — that is, we characterize the set of all possible behaviors that can result from a bounded error occurring at run time.

Erroneous Execution

32 Situations that result in erroneous execution (see 1.1.5).

Implementation Requirements

33 Additional requirements for conforming implementations.

33.a Discussion: ...as opposed to rules imposed on the programmer. An example might be, “The smallest representable duration, Duration'Small, shall not be greater than twenty milliseconds.”

33.b It's really just an issue of how the rule is worded. We could write the same rule as “The smallest representable duration is an implementation-defined value less than or equal to 20 milliseconds” and then it would be under “Static Semantics.”

Documentation Requirements

34 Documentation requirements for conforming implementations.

34.a Discussion: These requirements are beyond those that are implicitly specified by the phrase “implementation defined”. The latter require documentation as well, but we don't repeat these cases under this heading. Usually this heading is used for when the description of the documentation requirement is longer and does not correspond directly to one, narrow normative sentence.

Metrics

35 Metrics that are specified for the time/space properties of the execution of certain language constructs.

Implementation Permissions

36 Additional permissions given to the implementer.

36.a Discussion: For example, “The implementation is allowed to impose further restrictions on the record aggregates allowed in code statements.” When there are restrictions on the permission, those restrictions are given here also. For example, “An implementation is allowed to restrict the kinds of subprograms that are allowed to be main subprograms. However, it shall support at least parameterless procedures.” — we don't split this up between here and “Implementation Requirements.”

Implementation Advice

37 Optional advice given to the implementer. The word “should” is used to indicate that the advice is a recommendation, not a requirement. It is implementation defined whether or not a given recommendation is obeyed.
Implementation defined: Whether or not each recommendation given in Implementation Advice is followed — see M.3, “Implementation Advice” for a listing.

Discussion: The advice generally shows the intended implementation, but the implementer is free to ignore it. The implementer is the sole arbiter of whether or not the advice has been obeyed, if not, whether the reason is a good one, and whether the required documentation is sufficient. It would be wrong for the ACATS ACVC to enforce any of this advice.

For example, “Whenever possible, the implementation should choose a value no greater than fifty microseconds for the smallest representable duration, Duration'Small.”

We use this heading, for example, when the rule is so low level or implementation-oriented as to be untestable. We also use this heading when we wish to encourage implementations to behave in a certain way in most cases, but we do not wish to burden implementations by requiring the behavior.

NOTES
1 Notes emphasize consequences of the rules described in the (sub)clause or elsewhere. This material is informative.

Examples
Examples illustrate the possible forms of the constructs described. This material is informative.

Discussion:
The next three headings list all language changes between Ada 83 and Ada 95. Language changes are any change that changes the set of text strings that are legal Ada programs, or changes the meaning of any legal program. Wording changes, such as changes in terminology, are not language changes. Each language change falls into one of the following three categories:

Inconsistencies With Ada 83
This heading lists all of the upward inconsistencies between Ada 83 and Ada 95. Upward inconsistencies are situations in which a legal Ada 83 program is a legal Ada 95 program with different semantics. This type of upward incompatibility is the worst type for users, so we only tolerate it in rare situations.
(Note that the semantics of a program is not the same thing as the behavior of the program. Because of Ada's indeterminacy, the “semantics” of a given feature describes a set of behaviors that can be exhibited by that feature. The set can contain more than one allowed behavior. Thus, when we ask whether the semantics changes, we are asking whether the set of behaviors changes.)
This is not part of the definition of the language, and does not appear in the Ada 95, see Ada 2005, or Ada 2012 RM RM95.

Incompatibilities With Ada 83
This heading lists all of the upward incompatibilities between Ada 83 and Ada 95, except for the ones listed under “Inconsistencies With Ada 83” above. These are the situations in which a legal Ada 83 program is illegal in Ada 95. We do not generally consider a change that turns erroneous execution into an exception, or into an illegality, to be upwardly incompatible.
This is not part of the definition of the language, and does not appear in the Ada 95, see Ada 2005, or Ada 2012 RM RM95.

Extensions to Ada 83
This heading is used to list all upward compatible language changes; that is, language extensions. These are the situations in which a legal Ada 95 program is not a legal Ada 83 program. The vast majority of language changes fall into this category.
This is not part of the definition of the language, and does not appear in the Ada 95, see Ada 2005, or Ada 2012 RM RM95.

As explained above, the next heading does not represent any language change:

Wording Changes from Ada 83
This heading lists some of the nonsemantic changes between the Ada 83 RM RM83 and the Ada 95 RM RM95. It is incomplete; we have not attempted to list all wording changes, but only the “interesting” ones.
This is not part of the definition of the language, and does not appear in the Ada 95 or Ada 2005 or Ada 2012 RM.

Discussion:

The next three headings list all language changes between Ada 95 and Ada 2005 (the language defined by the Ada 95 standard plus Technical Corrigendum 1 plus Amendment 1). Each language change falls into one of the following three categories:

Inconsistencies With Ada 95

This heading lists all of the upward inconsistencies between Ada 95 and Ada 2005. Upward inconsistencies are situations in which a legal Ada 95 program is a legal Ada 2005 program with different semantics.

{AI05-0005-1} Inconsistencies marked with Corrigendum: are corrections to the original Ada 95 definition introduced by Corrigendum 1. Inconsistencies marked with Amendment Correction: are corrections to the original Ada 95 definition added by Amendment 1. Formally, these are inconsistencies caused by Ada Issues classified as Binding Interpretations; implementations of Ada 95 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not inconsistencies between Ada 95 and Ada 2005. Practically, however, they very well may be, as early Ada 95 implementations might not follow the recommendation. Inconsistencies so marked are not portable between Ada 95 implementations, while usually Ada 2005 will have more clearly defined behavior. Therefore, we document these for completeness.

This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.

Incompatibilities With Ada 95

This heading lists all of the upward incompatibilities between Ada 95 and Ada 2005, except for the ones listed under “Inconsistencies With Ada 95” above. These are the situations in which a legal Ada 95 program is illegal in Ada 2005.

{AI05-0005-1} As with inconsistencies, incompatibilities marked with Corrigendum: are corrections to the original Ada 95 definition introduced by Corrigendum 1. Incompatibilities marked with Amendment Correction: are corrections to the original Ada 95 definition added by Amendment 1. Formally, these are incompatibilities caused by Ada Issues classified as Binding Interpretations; implementations of Ada 95 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not incompatibilities between Ada 95 and Ada 2005. Practically, however, they very well may be, as early Ada 95 implementations might not follow the recommendation. Therefore, some Ada 95 implementations may be able to compile the examples, while others might not. In contrast, Ada 2005 compilers will have consistent behavior. Therefore, we document these for completeness.

This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.

Extensions to Ada 95

This heading is used to list all upward compatible language changes; that is, language extensions. These are the situations in which a legal Ada 2005 program is not a legal Ada 95 program. The vast majority of language changes fall into this category.

{AI05-0005-1} As with incompatibilities, extensions marked with Corrigendum: are corrections to the original Ada 95 definition introduced by Corrigendum 1. Extensions marked with Amendment Correction: are corrections to the original Ada 95 definition added by Amendment 1. Formally, these are extensions allowed by Ada Issues classified as Binding Interpretations. As corrections, implementations of Ada 95 are allowed to implement these extensions. Thus, these strictly speaking are not extensions of Ada 95; they’re part of Ada 95. Practically, however, they very well may be extensions, as early Ada 95 implementations might not implement the extension. Therefore, some Ada 95 implementations may be able to compile the examples, while others might not. In contrast, Ada 2005 compilers will always support the extensions. Therefore, we document these for completeness.

This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.

Discussion:

As explained above, the next heading does not represent any language change:

Wording Changes from Ada 95

This heading lists some of the nonsemantic changes between the Ada 95 RM and the Ada 2005 RM. This heading lists only “interesting” changes (for instance, editorial corrections are not listed). Changes which come from Technical Corrigendum 1 are marked Corrigendum; unmarked changes come from Amendment 1.

This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.
The next three headings list all language changes between Ada 2005 (the language defined by the Ada 95 standard plus Technical Corrigendum 1 plus Amendment 1) and Ada 2012 (the language defined by the third edition of the Standard). Each language change falls into one of the following three categories:

### Inconsistencies With Ada 2005

This heading lists all of the upward inconsistencies between Ada 2005 and Ada 2012. Upward inconsistencies are situations in which a legal Ada 2005 program is a legal Ada 2012 program with different semantics.

Inconsistencies marked with **Correction:** are corrections to the original Ada 2005 definition added by the third edition of the Standard. Formally, these are inconsistencies caused by Ada Issues classified as Binding Interpretations; implementations of Ada 2005 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not inconsistencies between Ada 2005 and Ada 2012. Practically, however, they very well may be, as early Ada 2005 implementations might not follow the recommendation. Inconsistencies so marked are not portable between Ada 2005 implementations, while usually Ada 2012 will have more clearly defined behavior. Therefore, we document these for completeness.

This is not part of the definition of the language, and does not appear in the Ada 2012 RM.

### Incompatibilities With Ada 2005

This heading lists all of the upward incompatibilities between Ada 2005 and Ada 2012, except for the ones listed under “Inconsistencies With Ada 2005” above. These are the situations in which a legal Ada 2005 program is illegal in Ada 2012.

As with inconsistencies, incompatibilities marked with **Correction:** are corrections to the original Ada 2005 definition added by the third edition. Formally, these are incompatibilities caused by Ada Issues classified as Binding Interpretations; implementations of Ada 2005 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not incompatibilities between Ada 2005 and Ada 2012. Practically, however, they very well may be, as early Ada 2005 implementations might not follow the recommendation. Therefore, some Ada 2005 implementations may be able to compile the examples, while others might not. In contrast, Ada 2012 compilers will have consistent behavior. Therefore, we document these for completeness.

This is not part of the definition of the language, and does not appear in the Ada 2012 RM.

### Extensions to Ada 2005

This heading is used to list all upward compatible language changes; that is, language extensions. These are the situations in which a legal Ada 2012 program is not a legal Ada 2005 program. The vast majority of language changes fall into this category.

As with incompatibilities, extensions marked with **Correction:** are corrections to the original Ada 2005 definition added by the third edition. Formally, these are extensions allowed by Ada Issues classified as Binding Interpretations. As corrections, implementations of Ada 2005 (and sometimes Ada 95) are allowed to implement these extensions. Thus, these strictly speaking are not extensions of Ada 2005; they’re part of Ada 2005. Practically, however, they very well may be extensions, as early Ada 2005 implementations might not implement the extension. Therefore, some Ada 2005 implementations may be able to compile the examples, while others might not. In contrast, Ada 2012 compilers will always support the extensions. Therefore, we document these for completeness.

This is not part of the definition of the language, and does not appear in the Ada 2012 RM.

---

As explained above, the next heading does not represent any language change:

### Wording Changes from Ada 2005

This heading lists some of the nonsemantic changes between the Ada 2005 RM and the Ada 2012 RM. This heading lists only “interesting” changes (for instance, editorial corrections are not listed). Items marked **Correction:** come from Ada Issues classified as Binding Interpretations and strictly speaking belong to Ada 2005; other items only belong to Ada 2012.

This is not part of the definition of the language, and does not appear in the Ada 2012 RM.
1.1.3 Conformity of an Implementation with the Standard

**Implementation Requirements**

A conforming implementation shall:

1. Translate and correctly execute legal programs written in Ada, provided that they are not so large as to exceed the capacity of the implementation;

2. Identify all programs or program units that are so large as to exceed the capacity of the implementation (or raise an appropriate exception at run time);

3. Identify all programs or program units that contain errors whose detection is required by this International Standard;

4. Supply all language-defined library units required by this International Standard;

5. Contain no variations except those explicitly permitted by this International Standard, or those that are impossible or impractical to avoid given the implementation's execution environment;

6. Specify all such variations in the manner prescribed by this International Standard.

**Discussion:** The *implementation* is the software and hardware that implements the language. This includes compiler, linker, operating system, hardware, etc.

We first define what it means to “conform” in general — basically, the implementation has to properly implement the normative rules given throughout the standard. Then we define what it means to conform to a Specialized Needs Annex — the implementation must support the core features plus the features of that Annex. Finally, we define what it means to “conform to the Standard” — this requires support for the core language, and allows partial (but not conflicting) support for the Specialized Needs Annexes.

**Implementation defined:** Capacity limitations of the implementation.

**Reason:** The “impossible or impractical” wording comes from AI-325. It takes some judgement and common sense to interpret this. Restricting compilation units to less than 4 lines is probably unreasonable, whereas restricting them to less than 4 billion lines is probably reasonable (at least given today's technology). We do not know exactly where to draw the line, so we have to make the rule vague.
The external effect of the execution of an Ada program is defined in terms of its interactions with its external environment. The following are defined as external interactions:

- Any interaction with an external file (see A.7);
- The execution of certain code_statements (see 13.8); which code_statements cause external interactions is implementation defined.

**Implementation defined:** Which code_statements cause external interactions.

- Any call on an imported subprogram (see Annex B), including any parameters passed to it;
- Any result returned or exception propagated from a main subprogram (see 10.2) or an exported subprogram (see Annex B) to an external caller;
- Any read or update of an atomic or volatile object (see C.6);
- The values of imported and exported objects (see Annex B) at the time of any other interaction with the external environment.

**To be honest:** {AI05-0229-1} Also other uses of imported and exported entities, as defined by the implementation, if the implementation supports such importing or exporting pragmas.

A conforming implementation of this International Standard shall produce for the execution of a given Ada program a set of interactions with the external environment whose order and timing are consistent with the definitions and requirements of this International Standard for the semantics of the given program.

**Ramification:** There is no need to produce any of the “internal effects” defined for the semantics of the program — all of these can be optimized away — so long as an appropriate sequence of external interactions is produced.

**Discussion:** See also 11.6 which specifies various liberties associated with optimizations in the presence of language-defined checks, that could change the external effects that might be produced. These alternative external effects are still consistent with the standard, since 11.6 is part of the standard.

Note that we only require “an appropriate sequence of external interactions” rather than “the same sequence...” An optimizer may cause a different sequence of external interactions to be produced than would be produced without the optimizer, so long as the new sequence still satisfies the requirements of the standard. For example, optimization might affect the relative rate of progress of two concurrent tasks, thereby altering the order in which two external interactions occur.

Note that the Ada 83 RM explicitly mentions the case of an “exact effect” of a program, but since so few programs have their effects defined exactly, we don't even mention this “special” case. In particular, almost any program that uses floating point or tasking has to have some level of inexactness in the specification of its effects. And if one includes aspects of the timing of the external interactions in the external effect of the program (as is appropriate for a real-time language), no “exact effect” can be specified. For example, if two external interactions initiated by a single task are separated by a “delay 1.0;” then the language rules imply that the two external interactions have to be separated in time by at least one second, as defined by the clock associated with the delay_relative_statement. This in turn implies that the time at which an external interaction occurs is part of the characterization of the external interaction, at least in some cases, again making the specification of the required “exact effect” impractical.

An implementation that conforms to this Standard shall support each capability required by the core language as specified. In addition, an implementation that conforms to this Standard may conform to one or more Specialized Needs Annexes (or to none). Conformance to a Specialized Needs Annex means that each capability required by the Annex is provided as specified.

**Discussion:** The last sentence defines what it means to say that an implementation conforms to a Specialized Needs Annex, namely, only by supporting all capabilities required by the Annex.

{AI05-0229-1} An implementation conforming to this International Standard may provide additional aspects, attributes, library units, and pragmas. However, it shall not provide any aspect, attribute, library unit, or pragma having the same name as an aspect, attribute, library unit, or pragma (respectively) specified in a Specialized Needs Annex unless the provided construct is either as specified in the
Specialized Needs Annex or is more limited in capability than that required by the Annex. A program that attempts to use an unsupported capability of an Annex shall either be identified by the implementation before run time or shall raise an exception at run time.

**Discussion:** The last sentence of the preceding paragraph defines what an implementation is allowed to do when it does not "conform" to a Specialized Needs Annex. In particular, the sentence forbids implementations from providing a construct with the same name as a corresponding construct in a Specialized Needs Annex but with a different syntax (e.g., an extended syntax) or quite different semantics. The phrase concerning "more limited in capability" is intended to give permission to provide a partial implementation, such as not implementing a subprogram in a package or having a restriction not permitted by an implementation that conforms to the Annex. For example, a partial implementation of the package Ada.Decimal might have Decimal.Max_Decimal_Digits as 15 (rather than the required 18). This allows a partial implementation to grow to a fully conforming implementation.

A restricted implementation might be restricted by not providing some subprograms specified in one of the packages defined by an Annex. In this case, a program that tries to use the missing subprogram will usually fail to compile. Alternatively, the implementation might declare the subprogram as abstract, so it cannot be called. Alternatively, a subprogram body might be implemented just to raise Program_Error. The advantage of this approach is that a program to be run under a fully conforming Annex implementation can be checked syntactically and semantically under an implementation that only partially supports the Annex. Finally, an implementation might provide a package declaration without the corresponding body, so that programs can be compiled, but partitions cannot be built and executed.

To ensure against wrong answers being delivered by a partial implementation, implementers are required to raise an exception when a program attempts to use an unsupported capability and this can be detected only at run time. For example, a partial implementation of Ada.Decimal might require the length of the Currency string to be 1, and hence, an exception would be raised if a subprogram were called in the package Edited_Output with a length greater than 1.

**Documentation Requirements**

Certain aspects of the semantics are defined to be either implementation defined or unspecified. In such cases, the set of possible effects is specified, and the implementation may choose any effect in the set. Implementations shall document their behavior in implementation-defined situations, but documentation is not required for unspecified situations. The implementation-defined characteristics are summarized in M.2.

**Discussion:** We used to use the term “implementation dependent” instead of “unspecified”. However, that sounded too much like “implementation defined”. Furthermore, the term “unspecified” is used in the ANSI C and POSIX standards for this purpose, so that is another advantage. We also use “not specified” and “not specified by the language” as synonyms for “unspecified.” The documentation requirement is the only difference between implementation defined and unspecified.

Note that the “set of possible effects” can be “all imaginable effects”, as is the case with erroneous execution.

The implementation may choose to document implementation-defined behavior either by documenting what happens in general, or by providing some mechanism for the user to determine what happens in a particular case.

**Documentation Requirement:** The behavior of implementations in implementation-defined situations shall be documented — see M.2, “Implementation-Defined Characteristics” for a listing.

**Implementation Advice**

If an implementation detects the use of an unsupported Specialized Needs Annex feature at run time, it should raise Program_Error if feasible.

**Implementation Advice:** Program_Error should be raised when an unsupported Specialized Needs Annex feature is used at run time.
Reason: The reason we don't require Program_Error is that there are situations where other exceptions might make sense. For example, if the Real Time Systems Annex requires that the range of System.Priority include at least 30 values, an implementation could conform to the Standard (but not to the Annex) if it supported only 12 values. Since the rules of the language require Constraint_Error to be raised for out-of-range values, we cannot require Program_Error to be raised instead.

If an implementation wishes to provide implementation-defined extensions to the functionality of a language-defined library unit, it should normally do so by adding children to the library unit.

Implementation Advice: Implementation-defined extensions to the functionality of a language-defined library unit should be provided by adding children to the library unit.

Implementation Note: If an implementation has support code (“run-time system code”) that is needed for the execution of user-defined code, it can put that support code in child packages of System. Otherwise, it has to use some trick to avoid polluting the user's namespace. It is important that such tricks not be available to user-defined code (not in the standard mode, at least) — that would defeat the purpose.

NOTES
2 The above requirements imply that an implementation conforming to this Standard may support some of the capabilities required by a Specialized Needs Annex without supporting all required capabilities.

Discussion: A conforming implementation can partially support a Specialized Needs Annex. Such an implementation does not conform to the Annex, but it does conform to the Standard.

1.1.4 Method of Description and Syntax Notation

The form of an Ada program is described by means of a context-free syntax together with context-dependent requirements expressed by narrative rules.

The meaning of Ada programs is described by means of narrative rules defining both the effects of each construct and the composition rules for constructs.

The context-free syntax of the language is described using a simple variant of Backus-Naur Form. In particular:

• Lower case words in a sans-serif font, some containing embedded underlines, are used to denote syntactic categories, for example:
  case_statement

• Boldface words are used to denote reserved words, for example:
  array

• Square brackets enclose optional items. Thus the two following rules are equivalent.

  {AI95-00433-01} simple_return_statement ::= return [expression];
  simple_return_statement ::= return; | return expression;

• Curly brackets enclose a repeated item. The item may appear zero or more times; the repetitions occur from left to right as with an equivalent left-recursive rule. Thus the two following rules are equivalent.

  term ::= factor {multiplying_operator factor}
  term ::= factor | term multiplying_operator factor

• A vertical line separates alternative items unless it occurs immediately after an opening curly bracket, in which case it stands for itself:

  constraint ::= scalar_constraint | composite_constraint
  discrete_choice_list ::= discrete_choice { | discrete_choice}

• If the name of any syntactic category starts with an italicized part, it is equivalent to the category name without the italicized part. The italicized part is intended to convey some semantic information. For example subtype_name and task_name are both equivalent to name alone.
14.1.4 Method of Description and Syntax Notation

Discussion: The grammar given in this International Standard is not LR(1). In fact, it is ambiguous; the ambiguities are resolved by the overload resolution rules (see 8.6).

We often use “if” to mean “if and only if” in definitions. For example, if we define “photogenic” by saying, “A type is photogenic if it has the following properties...,” we mean that a type is photogenic if and only if it has those properties. It is usually clear from the context, and adding the “and only if” seems too cumbersome.

When we say, for example, “a declarative item of a declarative_part”, we are talking about a declarative item immediately within that declarative_part. When we say “a declarative_item in, or within, a declarative_part”, we are talking about a declarative_item anywhere in the declarative_part, possibly deeply nested within other declarative_parts. (This notation doesn't work very well for names, since the name “of” something also has another meaning.)

When we refer to the name of a language-defined entity (for example, Duration), we mean the language-defined entity even in programs where the declaration of the language-defined entity is hidden by another declaration. For example, when we say that the expected type for the expression of a delay_relative_statement is Duration, we mean the language-defined type Duration that is declared in Standard, not some type Duration the user might have declared.

The delimiters, compound delimiters, reserved words, and numeric literals are exclusively made of the characters whose code position is between 16#20# and 16#7E#, inclusively. The special characters for which names are defined in this International Standard (see 2.1) belong to the same range. [For example, the character E in the definition of exponent is the character whose name is “LATIN CAPITAL LETTER E”, not “GREEK CAPITAL LETTER EPSILON”]

Discussion: This just means that programs can be written in plain ASCII characters; no characters outside of the 7-bit range are required.

When this International Standard mentions the conversion of some character or sequence of characters to upper case, it means the character or sequence of characters obtained by using simple upper case mapping locale-independent full case folding, as defined by documents referenced in the note in Clause section 1 of ISO/IEC 10646:20112003.

This paragraph was deleted Discussion: Unless otherwise specified for sequences of characters, case folding is applied to the sequence, not to individual characters. It sometimes can make a difference.

A syntactic category is a nonterminal in the grammar defined in BNF under “Syntax.” Names of syntactic categories are set in a different font, like this.

A construct is a piece of text (explicit or implicit) that is an instance of a syntactic category defined under “Syntax”.

Ramification: For example, an expression is a construct. A declaration is a construct, whereas the thing declared by a declaration is an “entity.”

Discussion: “Explicit” and “implicit” don't mean exactly what you might think they mean: The text of an instance of a generic is considered explicit, even though it does not appear explicitly (in the non-technical sense) in the program text, and even though its meaning is not defined entirely in terms of that text.

A constituent of a construct is the construct itself, or any construct appearing within it.

Whenever the run-time semantics defines certain actions to happen in an arbitrary order, this means that the implementation shall arrange for these actions to occur in a way that is equivalent to some sequential order, following the rules that result from that sequential order. When evaluations are defined to happen in an arbitrary order, with conversion of the results to some subtypes, or with some run-time checks, the evaluations, conversions, and checks may be arbitrarily interspersed, so long as each expression is evaluated before converting or checking its value. [Note that the effect of a program can depend on the order chosen by the implementation. This can happen, for example, if two actual parameters of a given call have side effects.]

Discussion: Programs will be more portable if their external effect does not depend on the particular order chosen by an implementation.
**Ramification:** Additional reordering permissions are given in 11.6, “Exceptions and Optimization”.

There is no requirement that the implementation always choose the same order in a given kind of situation. In fact, the implementation is allowed to choose a different order for two different executions of the same construct. However, we expect most implementations will behave in a relatively predictable manner in most situations.

**Reason:** The “sequential order” wording is intended to allow the programmer to rely on “benign” side effects. For example, if \( F \) is a function that returns a unique integer by incrementing some global and returning the result, a call such as \( P(F, F) \) is OK if the programmer cares only that the two results of \( F \) are unique; the two calls of \( F \) cannot be executed in parallel, unless the compiler can prove that parallel execution is equivalent to some sequential order.

### NOTES
3 The syntax rules describing structured constructs are presented in a form that corresponds to the recommended paragraphing. For example, an `if_statement` is defined as:

```plaintext
if_statement ::= if condition then sequence_of_statements
               { elsif condition then sequence_of_statements }
               [ else sequence_of_statements ] end if;
```

4 The line breaks and indentation in the syntax rules indicate the recommended line breaks and indentation in the corresponding constructs. The preferred places for other line breaks are after semicolons.

**Wording Changes from Ada 95**

- **{AI95-00285-01}** We now explicitly say that the lexical elements of the language (with a few exceptions) are made up of characters in the lower half of the Latin-1 character set. This is needed to avoid confusion given the new capability to use most ISO 10646 characters in identifiers and strings.

- **{AI95-00395-01}** We now explicitly define what the Standard means by upper case, as there are many possibilities for ISO 10646 characters.

- **{AI95-00433-01}** The example for square brackets has been changed as there is no longer a `return_statement` syntax rule.

**Wording Changes from Ada 2005**

- **{AI05-0227-1}** **Correction:** Upper case is defined by "simple upper case mapping", because "full case folding" is a mapping (mostly) to lower case.

### 1.1.5 Classification of Errors

**Implementation Requirements**

The language definition classifies errors into several different categories:

- Errors that are required to be detected prior to run time by every Ada implementation;

These errors correspond to any violation of a rule given in this International Standard, other than those listed below. In particular, violation of any rule that uses the terms shall, allowed, permitted, legal, or illegal belongs to this category. Any program that contains such an error is not a legal Ada program; on the other hand, the fact that a program is legal does not mean, *per se*, that the program is free from other forms of error.

The rules are further classified as either compile time rules, or post compilation rules, depending on whether a violation has to be detected at the time a compilation unit is submitted to the compiler, or may be postponed until the time a compilation unit is incorporated into a partition of a program.

**Ramification:** See, for example, 10.1.3, “Subunits of Compilation Units”; for some errors that are detected only after compilation. Implementations are allowed, but not required, to detect post compilation rules at compile time when possible.
• Errors that are required to be detected at run time by the execution of an Ada program;

The corresponding error situations are associated with the names of the predefined exceptions. Every Ada compiler is required to generate code that raises the corresponding exception if such an error situation arises during program execution. [If such an error situation is certain to arise in every execution of a construct, then an implementation is allowed (although not required) to report this fact at compilation time.]

• Bounded errors;

The language rules define certain kinds of errors that need not be detected either prior to or during run time, but if not detected, the range of possible effects shall be bounded. The errors of this category are called *bounded errors*. The possible effects of a given bounded error are specified for each such error, but in any case one possible effect of a bounded error is the raising of the exception Program_Error.

• Erroneous execution.

In addition to bounded errors, the language rules define certain kinds of errors as leading to *erroneous execution*. Like bounded errors, the implementation need not detect such errors either prior to or during run time. Unlike bounded errors, there is no language-specified bound on the possible effect of erroneous execution; the effect is in general not predictable.

**Ramification:** Executions are erroneous, not programs or parts of programs. Once something erroneous happens, the execution of the entire program is erroneous from that point on, and potentially before given possible reorderings permitted by 11.6 and elsewhere. We cannot limit it to just one partition, since partitions are not required to live in separate address spaces. (But implementations are encouraged to limit it as much as possible.)

Suppose a program contains a pair of things that will be executed “in an arbitrary order.” It is possible that one order will result in something sensible, whereas the other order will result in erroneous execution. If the implementation happens to choose the first order, then the execution is not erroneous. This may seem odd, but it is not harmful.

Saying that something is erroneous is semantically equivalent to saying that the behavior is unspecified. However, “erroneous” has a slightly more disapproving flavor.

**Implementation Permissions**

[ An implementation may provide *nonstandard modes* of operation. Typically these modes would be selected by a *pragma* or by a command line switch when the compiler is invoked. When operating in a nonstandard mode, the implementation may reject *compilation_units* that do not conform to additional requirements associated with the mode, such as an excessive number of warnings or violation of coding style guidelines. Similarly, in a nonstandard mode, the implementation may apply special optimizations or alternative algorithms that are only meaningful for programs that satisfy certain criteria specified by the implementation. In any case, an implementation shall support a *standard* mode that conforms to the requirements of this International Standard; in particular, in the standard mode, all legal *compilation_units* shall be accepted.]

**Discussion:** These permissions are designed to authorize explicitly the support for alternative modes. Of course, nothing we say can prevent them anyway, but this (redundant) paragraph is designed to indicate that such alternative modes are in some sense “approved” and even encouraged where they serve the specialized needs of a given user community, so long as the standard mode, designed to foster maximum portability, is always available.

**Implementation Advice**

If an implementation detects a bounded error or erroneous execution, it should raise Program_Error.

**Implementation Advice:** If a bounded error or erroneous execution is detected, Program_Error should be raised.

**Wording Changes from Ada 83**

Some situations that are erroneous in Ada 83 are no longer errors at all. For example, depending on the parameter passing mechanism when unspecified is possibly nonportable, but not erroneous.
Other situations that are erroneous in Ada 83 are changed to be bounded errors. In particular, evaluating an uninitialized scalar variable is a bounded error. The possible results are to raise Program_Error (as always), or to produce a machine-representable value (which might not be in the subtype of the variable). Violating a Range_Check or Overflow_Check raises Constraint_Error, even if the value came from an uninitialized variable. This means that optimizers can no longer “assume” that all variables are initialized within their subtype's range. Violating a check that is suppressed remains erroneous.

The “incorrect order dependences” category of errors is removed. All such situations are simply considered potential nonportabilities. This category was removed due to the difficulty of defining what it means for two executions to have a “different effect.” For example, if a function with a side effect is called twice in a single expression, it is not in principle possible for the compiler to decide whether the correctness of the resulting program depends on the order of execution of the two function calls. A compile time warning might be appropriate, but raising of Program_Error at run time would not be.

1.2 Normative References

Discussion: Unlike Fortran and COBOL, which added the Information technology prefix to the titles of their standard, C did not. This was confirmed in the list of standards titles on the ISO web site. No idea why ISO allowed that.
This paragraph was deleted.

Reason: {8652/0001} {AI95-00124-01} {AI95-00285-01} The Technical Corrigendum
1:1996 is needed so that character codes C6 and E6 (the ligatures Æ and æ) are considered letters. These were named
Latin Ligature AE in the original 1993 version, which would exclude them from being letters as defined in 2.1,
“Character Set.”

{AI95-00376-01} {AI05-0266-1} ISO/IEC 14882:20112003, Information technology — Programming
languages — C++.  

Discussion: This title is also missing the Information technology part. That was confirmed in the list of standards titles
on the ISO web site.

1.3 Terms and Definitions

Definitions

Terms are defined throughout this International Standard, indicated by italic type. Terms explicitly defined in this International Standard are not to be presumed to refer implicitly to similar terms defined elsewhere. Mathematical terms not defined in this International Standard are to be interpreted according to the CRC Concise Encyclopedia of Mathematics, Second Edition. Other terms not defined in this International Standard are to be interpreted according to the Webster's Third New International Dictionary of the English Language. Informal descriptions of some terms are also given in Annex N, “Glossary”.

Discussion: The index contains an entry for every defined term.

1.2 Normative References

The contents of the CRC Concise Encyclopedia of Mathematics, Second Edition can be accessed on

Glossary entry: Each term defined in Annex N is marked like this.

Discussion: Here are some AARM-only definitions: The Ada Rapporteur Group (ARG) interprets the Ada Reference
ManualRM83. An Ada Issue (AI) is a numbered ruling from the ARG. Ada Issues created for Ada 83 are denoted as
"AI83", while Ada Issues created for Ada 95 are denoted as "AI95" in this document. Similarly, Ada Issues created for
Ada 2005 are denoted as "AI05". The Ada Commentary Integration Document (ACID) is an edition of the Ada 83
RMRM83 in which clearly marked insertions and deletions indicate the effect of integrating the approved AIs. The
Uniformity Rapporteur Group (URG) issued recommendations intended to increase uniformity across Ada
implementations. The functions of the URG have been assumed by the ARG. A Uniformity Issue (UI) was a
numbered recommendation from the URG. A Defect Report and Response is an official query to WG9 about an error
in the standard. Defect Reports are processed by the ARG, and are referenced here by their ISO numbers: 8652/nnnn.
Most changes to the Ada 95 standard include reference(s) to the Defect Report(s) that prompted the change. The Ada
Conformity Assessment Test Suite (ACATS) is a set of tests intended to check the conformity of Ada implementations to
this standard. This set of tests was previously known as the Ada Compiler Validation Capability (ACVC).
2 Lexical Elements

{AI05-0299-1} [The text of a program consists of the texts of one or more compilations. The text of a compilation is a sequence of lexical elements, each composed of characters; the rules of composition are given in this clause. Pragmas, which provide certain information for the compiler, are also described in this clause.]

2.1 Character Set

{AI95-00285-01} {AI95-00395-01} {AI05-0266-1} The character repertoire for the text of an Ada program consists of the entire coding space described by the ISO/IEC 10646:2011 Universal Multiple-Octet Coded Character Set. This coding space is organized in planes, each plane comprising 65536 characters. Only characters allowed outside of comments are the graphic_characters and format_effectors.

This paragraph was deleted. Ramification: {AI95-00285-01} Any character, including an other_control_function, is allowed in a comment.

This paragraph was deleted. {AI95-00285-01} Note that this rule doesn't really have much force, since the implementation can represent characters in the source in any way it sees fit. For example, an implementation could simply define that what seems to be a nongraphic, non-format_effector character is actually a representation of the space character.

Discussion: {AI95-00285-01} {AI05-0266-1} It is our intent to follow the terminology of ISO/IEC 10646:2011 ISO-10646-1, “Character Handling”. Note that our definition for graphic_character is more inclusive than that of ISO 10646-1.

Syntax

Paragraphs 2 and 3 were deleted.

{AI95-00285-01} character ::= graphic_character | format_effector | other_control_function

{AI95-00285-01} graphic_character ::= identifier_letter | digit | space_character | special_character

{AI95-00285-01} {AI95-00395-01} {AI05-0266-1} A character is defined by this International Standard for each cell in the coding space described by ISO/IEC 10646:2011 ISO-10646-BMP where appropriate, and to remain compatible with the character classifications defined in A.3, “Character Handling”. Note that our definition for graphic_character is more inclusive than that of ISO 10646-1.

Static Semantics

{AI95-00285-01} {AI95-00395-01} {AI05-0079-1} {AI05-0262-1} {AI05-0266-1} The character repertoire for the text of an Ada program consists of the collection of characters described by the ISO/IEC 10646:20112002 called the Basic Multilingual Plane (BMP) of the ISO 10646 Universal Multiple Octet Coded Character Set, plus a set of format_effectors and, in comments only, a set of other_control_functions; the coded representation for these characters is implementation defined [it need not be a representation defined within ISO/IEC 10646:20112002 ISO-10646-1]. A character whose relative code point position in its plane is 16#FFE# or 16#FFF# is not allowed anywhere in the text of a program. The only characters allowed outside of comments are those in categories other_format, format_effector, and graphic_character.

Implementation defined: The coded representation for the text of an Ada program.

Ramification: {AI95-00285-01} Note that this rule doesn't really have much force, since the implementation can represent characters in the source in any way it sees fit. For example, an implementation could simply define that what seems to be an other_private_use character is actually a representation of the space character.
The semantics of an Ada program whose text is not in Normalization Form KC (as defined by Clause 21, section 24 of ISO/IEC 10646:2011) is implementation defined.

Implementation defined: The semantics of an Ada program whose text is not in Normalization Form KC.

The description of the language definition in this International Standard uses the character properties General Category, Simple Uppercase Mapping, Uppercase Mapping, and Special Case Condition of the documents referenced by the note in Clause 1 of ISO/IEC 10646:2011. These correspond to the graphic symbols of ISO 8859-1 (Latin-1); no graphic symbols are used in this International Standard for characters outside of Row 00 of the BMP. The actual set of graphic symbols used by an implementation for the visual representation of the text of an Ada program is not specified.

The categories of characters are categorized as follows:

Discussion: Our character classification considers that the cells not allocated in ISO/IEC 10646:2011 are graphic characters, except for those whose relative code point in their plane is 16#FFE# or 16#FFFF#. This seems to provide the best compatibility with future versions of ISO/IEC 10646, as future characters can be already be used in Ada character and string literals.

This paragraph was deleted.

Discussion: We use identifier_letter instead of simply letter because ISO 10646 BMP includes many other characters that would generally be considered "letters."

Any character whose General Category is defined to be “Letter, Uppercase” of Row 00 of ISO 10646 BMP whose name begins “Latin Capital Letter”.

Any character whose General Category is defined to be “Letter, Lowercase” of Row 00 of ISO 10646 BMP whose name begins “Latin Small Letter”.

This paragraph was deleted. To be honest: The above rules do not include the ligatures Æ and æ. However, the intent is to include these characters as identifier letters. This problem was pointed out by a comment from the Netherlands.

Any character whose General Category is defined to be “Letter, Titlecase”.

Any character whose General Category is defined to be “Letter, Modifier”.

Any character whose General Category is defined to be “Letter, Other”.

Any character whose General Category is defined to be “Mark, Non-Spacing”.

Any character whose General Category is defined to be “Mark, Spacing Combining”.

Any character whose General Category is defined to be “Number, Decimal” among the characters 0, 1, 2, 3, 4, 5, 6, 7, 8, or 9.

Any character whose General Category is defined to be “Number, Letter”.
Any character whose General Category is defined to be “Punctuation, Connector”.

Any character whose General Category is defined to be “Other, Format”.

Any character whose General Category is defined to be “Separator, Space”. The character of ISO 10646 BMP named “Space”.

Any character whose General Category is defined to be “Separator, Line” of the ISO 10646 BMP that is not reserved for a control function, and is not the space_character, an identifier_letter, or a digit.

Ramification: Note that the no break space and soft hyphen are special_characters, and therefore graphic_characters. They are not the same characters as space and hyphen-minus.

Any character whose General Category is defined to be “Separator, Paragraph”.

The characters whose code positions are 16#09# (CHARACTER TABULATION), 16#0A# (LINE FEED), 16#0B# (LINE TABULATION), 16#0C# (FORM FEED), 16#0D# (CARRIAGE RETURN), 16#85# (NEXT LINE), and the characters in categories separator_line and separator_paragraph control functions of ISO 6429 called character tabulation (HT), line tabulation (VT), carriage return (CR), line feed (LF), and form feed (FF).

Discussion: ISO/IEC 10646:2003 does not define the names of control characters, but rather refers to the names defined by ISO/IEC 6429:1992. These are the names that we use here.

Any character whose General Category is defined to be “Other, Control”, and which is not defined to be a format_effector.

Any character whose General Category is defined to be “Other, Private Use”.

Any character whose General Category is defined to be “Other, Surrogate”.

Any character that is not in the categories other_control, other_private_use, other_surrogate, format_effector, and whose relative code position in its plane is neither 16#FFFE# nor 16#FFFF#. Any control function, other than a format_effector, that is allowed in a comment; the set of other_control_functions allowed in comments is implementation defined.

This paragraph was deleted. Implementation defined: The control functions allowed in comments.

Discussion: We considered basing the definition of lexical elements on Annex A of ISO/IEC TR 10176 (4th edition), which lists the characters which should be supported in identifiers for all programming languages, but we finally decided against this option. Note that it is not our intent to diverge from ISO/IEC TR 10176, except to the extent that ISO/IEC TR 10176 itself diverges from ISO/IEC 10646:2003 (which is the case at the time of this writing [January 2005]).

More precisely, we intend to align strictly with ISO/IEC 10646:2003. It must be noted that ISO/IEC TR 10176 is a Technical Report while ISO/IEC 10646:2003 is a Standard. If one has to make a choice, one should conform with the Standard rather than with the Technical Report. And, it turns out that one must make a choice because there are important differences between the two:

- ISO/IEC TR 10176 is still based on ISO/IEC 10646:2000 while ISO/IEC 10646:2003 has already been published for a year. We cannot afford to delay the adoption of our amendment until ISO/IEC TR 10176 has been revised.
• There are considerable differences between the two editions of ISO/IEC 10646, notably in supporting characters beyond the BMP (this might be significant for some languages, e.g. Korean).

• ISO/IEC TR 10176 does not define case conversion tables, which are essential for a case-insensitive language like Ada. To get case conversion tables, we would have to reference either ISO/IEC 10646:2003 or Unicode, or we would have to invent our own.

For the purpose of defining the lexical elements of the language, we need character properties like categorization, as well as case conversion tables. These are mentioned in ISO/IEC 10646:2003 as useful for implementations, with a reference to Unicode. Machine-readable tables are available on the web at URLs:

http://www.unicode.org/Public/4.0-Update/UnicodeData-4.0.0.txt
http://www.unicode.org/Public/4.0-Update/CaseFolding-4.0.0.txt

with an explanatory document found at URL:
http://www.unicode.org/Public/4.0-Update/UCD-4.0.0.html

The actual text of the standard only makes specific references to the corresponding clauses of ISO/IEC 10646:2003, not to Unicode.

The following names are used when referring to certain characters (the first name is that given in ISO/IEC 10646:2003):

graphic symbol | name | graphic symbol | name
-----------------|-------|-----------------|-------
" | quotation mark | ; | colon
# | number sign | ; | semicolon
& | ampersand | < | less-than sign
' | apostrophe, tick | = | equals sign
( | left parenthesis | > | greater-than sign
) | right parenthesis | _ | low line, underline
* | asterisk, multiply | | vertical line
+ | plus sign | / | solidus, divide
, | comma | \ | left square bracket
- | hyphen-minus, minus | % | exclamation point
. | full stop, dot, point | | square bracket
\ | solidus, divide

Implementation Requirements

An Ada implementation shall accept Ada source code in UTF-8 encoding, with or without a BOM (see A.4.11), where every character is represented by its code point. The character pair CARRIAGE RETURN/LINE FEED (code points 16#0D# 16#0A#) signifies a single end of line (see 2.2); every other occurrence of a format effector other than the character whose code point position is 16#09# (CHARACTER TABULATION) also signifies a single end of line.

This is simply requiring that an Ada implementation be able to directly process the ACATS, which is provided in the described format. Note that files that only contain characters with code points in the first 128 (which is the majority of the ACATS) are represented in the same way in both UTF-8 and in “plain” string format. The ACATS includes a BOM in files that have any characters with code points greater than 127. Note that the BOM contains characters not legal in Ada source code, so an implementation can use that to automatically distinguish between files formatted as plain Latin-1 strings and UTF-8 with BOM.

We allow line endings to be both represented as the pair CR LF (as in Windows and the ACATS), and as single format effector characters (usually LF, as in Linux), in order that files created by standard tools on most operating systems can be correctly parsed.

Discussion: {AI95-00285-01} {AI05-0266-1} This table serves to show the correspondence between ISO/IEC 10646:2011 names and the graphic symbols (glyphs) used in this International Standard. These are the characters that play a special role in the syntax of Ada 95, or in the syntax rules; we don’t bother to define names for all characters. The first name given is the name from ISO 10646-1; the subsequent names, if any, are those used within the standard, depending on context.

graphic symbol | name | graphic symbol | name
-----------------|-------|-----------------|-------
" | quotation mark | ; | colon
# | number sign | ; | semicolon
& | ampersand | < | less-than sign
' | apostrophe, tick | = | equals sign
( | left parenthesis | > | greater-than sign
) | right parenthesis | _ | low line, underline
* | asterisk, multiply | | vertical line
+ | plus sign | / | solidus, divide
, | comma | \ | left square bracket
- | hyphen-minus, minus | % | exclamation point
. | full stop, dot, point | | square bracket
\ | solidus, divide
systems will meet the standard format. We specify how many line endings each represent so that compilers use the same line numbering for standard source files.

This requirement increases portability by having a format that is accepted by all Ada compilers. Note that implementations can support other source representations, including structured representations like a parse tree.

**Implementation Permissions**

\{AI95-00285-01\}, \{AI05-0266-1\} The categories defined above, as well as case mapping and folding, may be based on an implementation-defined version of ISO/IEC 10646 (2003 edition or later). In a nonstandard mode, the implementation may support a different character repertoire[; in particular, the set of characters that are considered `identifier_letter` can be extended or changed to conform to local conventions].

**Ramification:** If an implementation supports other character sets, it defines which characters fall into each category, such as `identifier_letter`, and what the corresponding rules of this section are, such as which characters are allowed in the text of a program.

The exact categories, case mapping, and case folding chosen affects identifiers, the result of `[[Wide_Wide_Image, and packages Wide_Characters.Handling and Wide_Wide_Characters.Handling.]

**Discussion:** This permission allows implementations to upgrade to using a newer character set standard whenever that makes sense, rather than having to wait for the next Ada Standard. But the character set standard used cannot be older than ISO/IEC 10646:2003 (which is essentially similar to Unicode 4.0).

**NOTES**

1. \{AI95-00285-01\} The characters in categories `other_control`, `other_private_use`, and `other_surrogate` are only allowed in comments. Every code position of ISO 10646 BMP that is not reserved for a control function is defined to be a `graphic_character` by this International Standard. This includes all code positions other than 0000 - 001F, 007F - 009F, and FF00 - FFFF.

2. \{AI05-0286-1\} The language does not specify the source representation of programs.

This paragraph was deleted. **Discussion:**--\{AI05-0286-1\} Any source representation is valid so long as the implementer can produce an (information-preserving) algorithm for translating both directions between the representation and the standard character set. (For example, every character in the standard character set has to be representable, even if the output devices attached to a given computer cannot print all of those characters properly.) From a practical point of view, every implementer will have to provide some way to process the ACATS/ACVC. It is the intent to allow source representations, such as parse trees, that are not even linear sequences of characters. It is also the intent to allow different fonts: reserved words might be in bold face, and that should be irrelevant to the semantics.

**Extensions to Ada 83**

Ada 95 allows 8-bit and 16-bit characters, as well as implementation-specified character sets.

**Wording Changes from Ada 83**

\{AI95-00285-01\}, \{AI05-0299-1\}, \{AI05-0299-01\} The syntax rules in this subclause are modified to remove the emphasis on basic characters vs. others. (In this day and age, there is no need to point out that you can write programs without using (for example) lower case letters.) In particular, `character` (representing all characters usable outside comments) is added, and `basic_graphic_character`, `other_special_character`, and `basic_character` are removed. `Special_character` is expanded to include Ada 83's `other_special_character`, as well as new 8-bit characters not present in Ada 83. **Ada 2005 removes `special_character` altogether; we want to stick to ISO/IEC 10646:2003 character classifications.** Note that the term “basic letter” is used in A.3, “Character Handling” to refer to letters without diacritical marks.

This paragraph was deleted. **Discussion:**--\{AI95-00285-01\} We use `identifier_letter` rather than letter since ISO-10646 BMP includes many “letters” that are not permitted in identifiers (in the standard mode).

**Extensions to Ada 95**

\{AI95-00285-01\}, \{AI95-00395-01\}, \{AI95-00395-01\} Program text can use most characters defined by ISO-10646:2003. This subclause has been rewritten to use the categories defined in that Standard. This should ease programming in languages other than English.

**Inconsistencies With Ada 2005**

\{AI05-0299-1\}, \{AI05-0266-1\} An implementation is allowed (but not required) to use a newer character set standard to determine the categories, case mapping, and case folding. Doing so will change the results of attributes...
Image and the packages Wide_Characters.Handling in the case of a few rarely used characters. (This also could make some identifiers illegal, for characters that are no longer classified as letters.) This is unlikely to be a problem in practice. Moreover, truly portable Ada 2012 programs should avoid using in these contexts any characters that would have different classifications in any character set standards issued since 10646.2003 (since the compiler can use any such standard as the basis for its classifications).

Wording Changes from Ada 2005

\{AI05-0079-1\} Correction: Clarified that only characters in the categories defined here are allowed in the source of an Ada program. This was clear in Ada 95, but Amendment 1 dropped the wording instead of correcting it.

\{AI05-0286-1\} A standard source representation is defined that all compilers are expected to process. Since this is the same format as the ACATS, it seems unlikely that there are any implementations that don't meet this requirement. Moreover, other representations are still permitted, and the "impossible or impractical" loophole (see 1.1.3) can be invoked for any implementations that cannot directly process the ACATS.

2.2 Lexical Elements, Separators, and Delimiters

Static Semantics

The text of a program consists of the texts of one or more compilations. The text of each compilation is a sequence of separate lexical elements. Each lexical element is formed from a sequence of characters, and is either a delimiter, an identifier, a reserved word, a numeric_literal, a character_literal, a string_literal, or a comment. The meaning of a program depends only on the particular sequences of lexical elements that form its compilations, excluding comments.

\{AI95-00285-01\} \{AI05-0262-1\} The text of a compilation is divided into lines. In general, the representation for an end of line is implementation defined. However, a sequence of one or more format_effectors other than the_character_whose_code_position is 16#09# (CHARACTER TABULATION) character tabulation (HT) signifies at least one end of line.

Implementation defined: The representation for an end of line.

\{AI95-00285-01\} \{AI05-0262-1\} A separator is any of a separator_space space character, a format_effector format effector, or the end of a line, as follows:

Discussion: It might be useful to define "white space" and use it here.

- A separator_space is a separator except within a comment, a string_literal, or a character_literal.
- The character whose code_position is 16#09# (CHARACTER TABULATION) character tabulation (HT) is a separator except within a comment.
- The end of a line is always a separator.

One or more separators are allowed between any two adjacent lexical elements, before the first of each compilation, or after the last. At least one separator is required between an identifier, a reserved word, or a numeric_literal and an adjacent identifier, reserved word, or numeric_literal.

\{AI05-0079-1\} One or more other format characters are allowed anywhere that a separator is; any such characters have no effect on the meaning of an Ada program.

\{AI95-00285-01\} A delimiter is either one of the following special characters:

| & | ' | ( | ) | * | + | - | . | / | : | ; | < | = | > |

or one of the following compound delimiters each composed of two adjacent special characters

| => | .. | ** | := | /= | >= | <= | << | >> | <> |
Each of the special characters listed for single character delimiters is a single delimiter except if this character is used as a character of a compound delimiter, or as a character of a comment, string_literal, character_literal, or numeric_literal.

The following names are used when referring to compound delimiters:

- `=>` arrow
- `..` double dot
- `**` double star, exponentiate
- `:=` assignment (pronounced: “becomes”)
- `/=` inequality (pronounced: “not equal”)
- `>=` greater than or equal
- `<=` less than or equal
- `<=` left label bracket
- `>>` right label bracket
- `<>` box

**Implementation Requirements**

An implementation shall support lines of at least 200 characters in length, not counting any characters used to signify the end of a line. An implementation shall support lexical elements of at least 200 characters in length. The maximum supported line length and lexical element length are implementation defined.

**Implementation defined:** Maximum supported line length and lexical element length.

**Discussion:** From URG recommendation.

Wording Changes from Ada 95

{AI95-00285-01} {AI95-00395-01} The wording was updated to use the new character categories defined in the preceding subclause.

Extensions to Ada 2005

{AI05-0079-1} **Correction:** Clarified that other_format characters are allowed anywhere that separators are allowed. This was intended in Ada 2005, but didn't actually make it into the wording.

### 2.3 Identifiers

Identifiers are used as names.

**Syntax**

{AI95-00285-01} {AI95-00395-01} `identifier ::= identifier_start {identifier_start | identifier_extend} identifier_letter {underline} letter_or_digit`

2.3 Identifiers

13 December 2012      26

\{AI95-00285-01\} {AI95-00395-01\} identifier_startletter_or_digit ::= 
  letter_uppercase
  | letter_lowercase
  | letter_titlecase
  | letter_modifier
  | letter_other
  | number_lettidenter_letter | digit

\{AI95-00285-01\} {AI95-00395-01\} {AI05-0091-1\} identifier_extend ::= 
  mark_non_spacing
  | mark_spacing_combining
  | number_decimal
  | punctuation_connector
  | other_format

\{AI95-00285-01\} {AI95-00395-01\} {AI05-0091-1\} AnAfter eliminating the characters in category other--format, an
identifier shall not contain two consecutive characters in category
punctuation_connector, punctuation_connector, or end with a character in that category.An identifier
shall not be a reserved word.

Reason: This rule was stated in the syntax in Ada 95, but that has gotten too complex in Ada 2005. Since other--format
characters usually do not display, we do not want to count them as separating two underscores.

Static Semantics

\{AI95-00285-01\} {AI95-00395-01\} {AI05-0091-1\} Two identifiers are
considered the same if they consist of the same sequence of characters after applying locale-independent
simple case folding, as defined by documents referenced in the note in Clause 1 of ISO/IEC
10646:2011 the following transformations (in this order):All characters of an
identifier are significant, including any underline character. Identifiers differing only in the use of corresponding upper and lower
case letters are considered the same.

- \{AI95-00285-01\} {AI05-0091-1\} The characters in category other--format are eliminated.

- \{AI95-00285-01\} {AI95-00395-01\} {AI05-0091-1\} The remaining sequence of characters is
converted to upper case.

Discussion: \{AI05-0227-1\} Simple case folding is a mapping to lower case, so this is matching the defining (lower case)
version of a reserved word. We could have mentioned case folding of the reserved words, but as that is an
identity function, it would have no effect.Two of the letters of ISO 8859--1 appear only as lower case, “sharp s” and “y
with diaeresis.” These two letters have no corresponding upper case letter (in particular, they are not considered
equivalent to one another).

- \{AI05-0227-1\} The “documents referenced” means Unicode. Note that simple case folding is supposed to be
compatible between Unicode versions, so the Unicode version used doesn't matter.

- \{AI95-00285-01\} {AI95-00395-01\} {AI05-0091-1\} After applying simple case folding these
transformations, an identifier shall not be identical to a reserved word (in upper case).

Implementation Note: We match the reserved words after applying case folding doing these transformations so that
the rules for identifiers and reserved words are the same. (This allows other--format characters, which usually don't
display, in a reserved word without changing it to an identifier.) Since a compiler usually will lexically process
identifiers and reserved words the same way (often with the same code), this will prevent a lot of headaches.

Ramification: \{AI05-0227-1\} The rules for reserved words differ in one way: they define case conversion on letters
rather than sequences. This means that it is possible that there exist some unusual sequences that are neither identifiers
nor reserved words. We are not aware of any such sequences so long as we use simple case folding (as opposed to full
case folding), but we have defined the rules in case any are introduced in future character set standards. This originally
was a problem when converting to upper case:For instance, “if” and “acceSS” have upper case conversions of “IF” and
“ACCESS” respectively. We would not want these to be treated as reserved words. But neither of these cases exist
when using simple case folding. These are not identifiers, because the transformed values are identical to a reserved
word. But they are not reserved words, either, because the original values do not match any reserved word as defined
or with any number of characters of the reserved word in upper case. Thus, these odd constructions are just illegal, and
should not appear in the source of a program.

Implementation Permissions

In a nonstandard mode, an implementation may support other upper/lower case equivalence rules for
identifiers[, to accommodate local conventions].

Discussion: \{AI95-00285-01\} \{AI05-0227-1\} For instance, in most languages, the simple case folded uppercase
equivalent of LATIN CAPITAL SMALL LETTER I (a lower case letter without with a dot above) is LATIN
SMALL CAPITAL LETTER I (a lower case letter with without a dot above). In Turkish, though, LATIN
CAPITAL SMALL LETTER I and LATIN CAPITAL SMALL LETTER DOTLESS I WITH DOT ABOVE are two
distinct letters, so the case folded uppercase equivalent of LATIN CAPITAL SMALL LETTER I is LATIN
SMALL CAPITAL LETTER DOTLESS I WITH DOT ABOVE, and the case folded uppercase equivalent of LATIN
CAPITAL SMALL LETTER DOTLESS I WITH DOT ABOVE is LATIN SMALL CAPITAL LETTER I. Take for
instance the following identifier (which is the name of a city on the Tigris river in Eastern Anatolia):

```
DIYARBAKIR
```

-- The first i is dotted, the second isn't

A Turkish reader would expect that the above identifier is equivalent to Locale-independent conversion to upper case
results in:

```
diyarbakir
```

-- Both Is are dotted.

However, locale-independent simple case folding (and thus Ada) maps this to:

```
diyarbakir
```

which is different from any of the following identifiers: This means that the four following sequences of characters
represent the same identifier, even though for a locutor of Turkish they would probably be considered distinct words:

```
diyarbakir
diyarbakir
diyarbakir
diyarbakir
```

including the “correct” matching identifier for Turkish. Upper case conversion (used in \Wide/Wide_Image)
introduces additional problems.

An implementation targeting the Turkish market is allowed (in fact, expected) to provide a nonstandard mode where
case folding is appropriate for Turkish. This would cause the original identifier to be converted to:

```
DIYARBAKIR
```

-- The first i is dotted, the second isn't.

and the four sequences of characters shown above would represent four distinct identifiers.

Lithuanian and Azeri are two other languages that present similar idiosyncrasies.

NOTES
3 \{AI95-00285-01\} Identifiers differing only in the use of corresponding upper and lower case letters are considered the
same.

Examples of identifiers:

```
{AI95-00433-01} Count X Get_Symbol Ethelyn Marion
Snobol_4 XI Page_Count Store_Next_Item
Платон -- Plato
Чайковский -- Tchaikovsky
θ φ -- Angles
```

Wording Changes from Ada 83

We no longer include reserved words as identifiers. This is not a language change. In Ada 83, identifier included
reserved words. However, this complicated several other rules (for example, regarding implementation-defined
attributes and pragmas, etc.). We now explicitly allow certain reserved words for attribute designators, to make up for
the loss.

Ramification: Because syntax rules are relevant to overload resolution, it means that if it looks like a reserved word, it
is not an identifier. As a side effect, implementations cannot use reserved words as implementation-defined attributes
or pragma names.
2.3 Identifiers

Extensions to Ada 95

8.c/2  {AI95-00285-01} An identifier can use any letter defined by ISO-10646:2003, along with several other categories. This should ease programming in languages other than English.

Incompatibilities With Ada 2005

8.d/3  {AI05-0091-1} Correction: other_format characters were removed from identifiers as the Unicode recommendations have changed. This change can only affect programs written for the original Ada 2005, so there should be few such programs.

8.e/3  {AI05-0227-1} Correction: We now specify simple case folding rather than full case folding. That potentially could change identifier equivalence, although it is more likely that identifiers that are considered the same in original Ada 2005 will now be considered different. This change was made because the original Ada 2005 definition was incompatible (and even inconsistent in unusual cases) with the Ada 95 identifier equivalence rules. As such, the Ada 2005 rules were rarely fully implemented, and in any case, only Ada 2005 identifiers containing wide characters could be affected.

2.4 Numeric Literals

There are two kinds of numeric_literals, real literals and integer literals. A real literal is a numeric_literal that includes a point; an integer literal is a numeric_literal without a point.

Syntax

numeric_literal ::= decimal_literal | based_literal

NOTES

4  The type of an integer literal is universal_integer. The type of a real literal is universal_real.

2.4.1 Decimal Literals

A decimal_literal is a numeric_literal in the conventional decimal notation (that is, the base is ten).

Syntax

decimal_literal ::= numeral [.numeral] [exponent]
numeral ::= digit {[underline] digit}
exponent ::= E [+|-] numeral | E – numeral

{AI95-00285-01} digit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9

An exponent for an integer literal shall not have a minus sign.

5.a  Ramification: Although this rule is in this subclause, it applies also to the next subclause.

Static Semantics

6  An underline character in a numeric_literal does not affect its meaning. The letter E of an exponent can be written either in lower case or in upper case, with the same meaning.

6.a  Ramification: Although these rules are in this subclause, they apply also to the next subclause.

7  An exponent indicates the power of ten by which the value of the decimal_literal without the exponent is to be multiplied to obtain the value of the decimal_literal with the exponent.

Examples

Examples of decimal literals:

<table>
<thead>
<tr>
<th>Example</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>12</td>
<td>integer literals</td>
</tr>
<tr>
<td>12.0</td>
<td>real literals</td>
</tr>
<tr>
<td>0.456</td>
<td>REAL 3.14159_26</td>
</tr>
</tbody>
</table>

8
We have changed the syntactic category name integer to be numeral. We got this idea from ACID. It avoids the confusion between this and integers. (Other places don't offer similar confusions. For example, a string_literal is different from a string.)

2.4.2 Based Literals

[A based_literal is a numeric_literal expressed in a form that specifies the base explicitly.]

Syntax

\[
\text{based\_literal ::= base \# based\_numeral \[.based\_numeral\] \# \[exponent\]}
\]

base ::= numeral

based\_numeral ::= extended\_digit \{[underline]\} extended\_digit

extended\_digit ::= digit | A | B | C | D | E | F

Legality Rules

The base (the numeric value of the decimal numeral preceding the first #) shall be at least two and at most sixteen. The extended\_digits A through F represent the digits ten through fifteen, respectively. The value of each extended\_digit of a based\_literal shall be less than the base.

Static Semantics

The conventional meaning of based notation is assumed. An exponent indicates the power of the base by which the value of the based\_literal without the exponent is to be multiplied to obtain the value of the based\_literal with the exponent. The base and the exponent, if any, are in decimal notation.

The extended\_digits A through F can be written either in lower case or in upper case, with the same meaning.

Examples of based\_literals:

\[
\begin{align*}
2\#1111\_1111\# & \quad 16\#FF\# & \quad 016\#0ff\# & \quad \text{integer\_literals of value 255} \\
16\#E\#E1 & \quad 2\#1110\_0000\# & \quad \text{integer\_literals of value 224} \\
16\#F.FF\#E+2 & \quad 2\#1.1111\_1110\_1110\#E11 & \quad \text{real\_literals of value 4095.0}
\end{align*}
\]

Wording Changes from Ada 83

The rule about which letters are allowed is now encoded in BNF, as suggested by Mike Woodger. This is clearly more readable.

2.5 Character Literals

[A character\_literal is formed by enclosing a graphic character between two apostrophe characters.]

Syntax

\[
\text{character\_literal ::= 'graphic\_character'}
\]

NOTES

5 A character\_literal is an enumeration literal of a character type. See 3.5.2.
Examples

Examples of character literals:

```
{AI95-00433-01} 'Å' 'ß' '*' ' ' 
'Ñ' 'Ñ' 'Λ' -- Various els. 
∞ -- Big numbers - infinity and aleph.
```

Wording Changes from Ada 83

{AI05-0299-1} The definitions of the values of literals are in Clauses Sections 3 and 4, rather than here, since it requires knowledge of types.

2.6 String Literals

A string_literal is formed by a sequence of graphic characters (possibly none) enclosed between two quotation marks used as string brackets. They are used to represent operator_symbols (see 6.1), values of a string type (see 4.2), and array subaggregates (see 4.3.3).

Syntax

```
string_literal ::= "{string_element}"
string_element ::= "" | non_quotation_mark_graphic_character
```

A string_element is either a pair of quotation marks (""), or a single graphic_character other than a quotation mark.

Static Semantics

The sequence of characters of a string_literal is formed from the sequence of string_elements between the bracketing quotation marks, in the given order, with a string_element that is "" becoming a single quotation mark in the sequence of characters, and any other string_element being reproduced in the sequence.

A null string literal is a string_literal with no string_elements between the quotation marks.

NOTES

6 An end of line cannot appear in a string_literal.

Examples

Examples of string literals:

```
{AI95-00433-01} "Message of the day:"
"
" " "A" " "" -- a null string literal
" " " " " " " " " " -- three string literals of length 1

"Characters such as $, %, and } are allowed in string literals"
"Archimedes said ""Eúonxy"""
"Volume of cylinder (πr²h) = ""
```

Wording Changes from Ada 83

{AI95-00285-01} No transformation is performed on the sequence of characters of a string_literal.

NOTES

6 An end of line cannot appear in a string_literal.

Examples

Examples of string literals:

```
{AI95-00433-01} "Message of the day:"
"
" " "A" " "" -- a null string literal
" " " " " " " " " -- three string literals of length 1

"Characters such as $, %, and } are allowed in string literals"
"Archimedes said ""Eúonxy"""
"Volume of cylinder (πr²h) = ""
```

Wording Changes from Ada 83

{AI95-00285-01} No transformation is performed on the sequence of characters of a string_literal.

NOTES

6 An end of line cannot appear in a string_literal.

Examples

Examples of string literals:

```
{AI95-00433-01} "Message of the day:"
"
" " "A" " "" -- a null string literal
" " " " " " " " " -- three string literals of length 1

"Characters such as $, %, and } are allowed in string literals"
"Archimedes said ""Eúonxy"""
"Volume of cylinder (πr²h) = ""
```

Wording Changes from Ada 83

{AI95-00285-01} No transformation is performed on the sequence of characters of a string_literal.

NOTES

6 An end of line cannot appear in a string_literal.

Examples

Examples of string literals:

```
{AI95-00433-01} "Message of the day:"
"
" " "A" " "" -- a null string literal
" " " " " " " " " -- three string literals of length 1

"Characters such as $, %, and } are allowed in string literals"
"Archimedes said ""Eúonxy"""
"Volume of cylinder (πr²h) = ""
```

Wording Changes from Ada 83

{AI95-00285-01} No transformation is performed on the sequence of characters of a string_literal.
2.7 Comments

A comment starts with two adjacent hyphens and extends up to the end of the line.

Syntax

comment ::= --{non_end_of_line_character}

A comment may appear on any line of a program.

Static Semantics

The presence or absence of comments has no influence on whether a program is legal or illegal. Furthermore, comments do not influence the meaning of a program; their sole purpose is the enlightenment of the human reader.

Examples

Examples of comments:

-- the last sentence above echoes the Algol 68 report
end;  -- processing of Line is complete
-- a long comment may be split onto
-- two or more consecutive lines
---------------- the first two hyphens start the comment

2.8 Pragmas

A pragma is a compiler directive. There are language-defined pragmas that give instructions for optimization, listing control, etc. An implementation may support additional (implementation-defined) pragmas.

Language Design Principles

{AI05-0100-1} {AI05-0163-1} In general, if all pragmas are treated as unrecognized pragmas, the program should remain both syntactically and semantically legal. There are a few exceptions to this general principle (for example, pragma Import can eliminate the need for a completion), but the principle remains, and is strictly true at the syntactic level. Certainly any implementation-defined pragmas should obey this principle both syntactically and semantically, so that if the pragmas are not recognized by some other implementation, the program will remain legal.

Syntax

pragma ::= 
pragma identifier [(pragma_argument_association [, pragma_argument_association])];

{AI05-0290-1} pragma_argument_association ::= 
| [pragma_argument_identifier =>] name
| [pragma_argument_identifier =>] expression
| pragma_argument aspect_mark => name
| pragma_argument aspect_mark => expression

{AI05-0290-1} In a pragma, any pragma_argument_associations without a
pragma_argument_identifier or pragma_argument_aspect_mark shall precede any associations with
a pragma_argument_identifier or pragma_argument_aspect_mark.

Pragmas are only allowed at the following places in a program:

- After a semicolon delimiter, but not within a formal_part or discriminant_part.
The name of a pragma is the identifier following the reserved word pragma. The name or expression of a pragma argument association is a pragma argument.

To be honest: For compatibility with Ada 83, the name of a pragma may also be "interface", which is not an identifier (because it is a reserved word). See J.12.

An identifier specific to a pragma is an identifier or reserved word that is used in a pragma argument with special meaning for that pragma.

To be honest: Whenever the syntax rules for a given pragma allow "identifier" as an argument of the pragma, that identifier is an identifier specific to that pragma.

In a few cases, a reserved word is allowed as "an identifier specific to a pragma". Even in these cases, the syntax still is written as identifier (the reserved words are not shown). For example, the restriction No Use Of Attribute (see 13.12.1) allows the reserved words which can be attribute designators, but the syntax for a restriction does not include these reserved words.

Static Semantics

If an implementation does not recognize the name of a pragma, then it has no effect on the semantics of the program. Inside such a pragma, the only rules that apply are the Syntax Rules.

This rule takes precedence over any other rules that imply otherwise.

Note well: this rule applies only to pragmas whose name is not recognized. If anything else is wrong with a pragma (at compile time), the pragma is illegal. This is true whether the pragma is language defined or implementation defined.

For example, an expression in an unrecognized pragma does not cause freezing, even though the rules in 13.14, "Freezing Rules" say it does; the above rule overrules those other rules. On the other hand, an expression in a recognized pragma causes freezing, even if this makes something illegal.

For another example, an expression that would be ambiguous is not illegal if it is inside an unrecognized pragma.

Note, however, that implementations have to recognize pragma Inline(Foo) and freeze things accordingly, even if they choose to never do inlining.

Obviously, the contradiction needs to be resolved one way or the other. The reasons for resolving it this way are: The implementation is simple — the compiler can just ignore the pragma altogether. The interpretation of constructs appearing inside implementation-defined pragmas is implementation defined. For example: "pragma Mumble(X);". If the current implementation has never heard of Mumble, then it doesn't know whether X is a name, an expression, or an identifier specific to the pragma Mumble.

The syntax of individual pragmas overrides the general syntax for pragma.

This also implies that named associations do not allow one to give the arguments in an arbitrary order — the order given in the syntax rule for each individual pragma must be obeyed. However, it is generally possible to leave out earlier arguments when later ones are given; for example, this is allowed by the syntax rule for pragma Import (see J.15.5, "Interfacing Pragmas" and B.1, "Interfacing Aspects"). As for subprogram calls, positional notation precedes named notation.
Note that Ada 83 had no pragmas for which the order of named associations mattered, since there was never more than one argument that allowed named associations.

To be honest: The interpretation of the arguments of implementation-defined pragmas is implementation defined. However, the syntax rules have to be obeyed.

**Dynamic Semantics**

Any **pragma** that appears at the place of an executable construct is executed. Unless otherwise specified for a particular pragma, this execution consists of the evaluation of each evaluable pragma argument in an arbitrary order.

**Ramification:** For a **pragma** that appears at the place of an elaborable construct, execution is elaboration.

An identifier specific to a **pragma** is neither a **name** nor an **expression** — such identifiers are not evaluated (unless an implementation defines them to be evaluated in the case of an implementation-defined **pragma**).

The “unless otherwise specified” part allows us (and implementations) to make exceptions, so a **pragma** can contain an expression that is not evaluated. Note that **pragmas** in **type_definitions** may contain expressions that depend on discriminants.

When we wish to define a **pragma** with some run-time effect, we usually make sure that it appears in an executable context; otherwise, special rules are needed to define the run-time effect and when it happens.

**Implementation Requirements**

The implementation shall give a warning message for an unrecognized **pragma** name.

**Ramification:** An implementation is also allowed to have modes in which a warning message is suppressed, or in which the presence of an unrecognized **pragma** is a compile-time error.

**Implementation Permissions**

An implementation may provide implementation-defined pragmas; the name of an implementation-defined **pragma** shall differ from those of the language-defined **pragmas**.

**Implementation defined:** Implementation-defined **pragmas**.

**Ramification:** The semantics of implementation-defined **pragmas**, and any associated rules (such as restrictions on their placement or arguments), are, of course, implementation defined. Implementation-defined **pragmas** may have run-time effects.

An implementation may ignore an unrecognized **pragma** even if it violates some of the Syntax Rules, if detecting the syntax error is too complex.

**Reason:** Many compilers use extra post-parsing checks to enforce the syntax rules, since the Ada syntax rules are not LR(k) (for any k). (The grammar is ambiguous, in fact.) This paragraph allows them to ignore an unrecognized **pragma**, without having to perform such post-parsing checks.

**Implementation Advice**

Normally, implementation-defined **pragmas** should have no semantic effect for error-free programs; that is, if the implementation-defined **pragmas** in a working program are replaced with unrecognized **pragmas** removed from a working program, the program should still be legal, and should still have the same semantics.

**Implementation Advice:** Implementation-defined **pragmas** should have no semantic effect for error-free programs.

**Ramification:** Note that “semantics” is not the same as “effect;” as explained in 1.1.3, the semantics defines a set of possible effects.

Note that adding a **pragma** to a program might cause an error (either at compile time or at run time). On the other hand, if the language-specified semantics for a feature are in part implementation defined, it makes sense to support **pragmas** that control the feature, and that have real semantics; thus, this paragraph is merely a recommendation.

Normally, an implementation should not define **pragmas** that can make an illegal program legal, except as follows:

- **{A105-0229-1}** A **pragma** used to complete a declaration, such as a **pragma** **Import**,
Discussion: \{AI05-0229-1\} There are no language-defined pragmas which can be completions; \texttt{pragma Import} was defined this way in Ada 95 and Ada 2005, but in Ada 2012 \texttt{pragma Import} just sets aspect \texttt{Import} which disallows having any completion.

- A pragma used to configure the environment by adding, removing, or replacing \texttt{library_items}.

Implementation Advice: Implementation-defined pragmas should not make an illegal program legal, unless they complete a declaration or configure the \texttt{library_items} in an environment.

Ramification: For example, it is OK to support \texttt{Interface}, \texttt{System_Name}, \texttt{Storage_Unit}, and \texttt{Memory_Size} pragmas for upward compatibility reasons, even though all of these pragmas can make an illegal program legal. (The latter three can affect legality in a rather subtle way: They affect the value of named numbers in System, and can therefore affect the legality in cases where static expressions are required.)

On the other hand, adding implementation-defined pragmas to a legal program can make it illegal. For example, a common kind of implementation-defined pragma is one that promises some property that allows more efficient code to be generated. If the promise is a lie, it is best if the user gets an error message.

Incompatibilities With Ada 83

In Ada 83, “bad” pragmas are ignored. In Ada 95, they are illegal, except in the case where the name of the pragma itself is not recognized by the implementation.

Extensions to Ada 83

Implementation-defined pragmas may affect the legality of a program.

Wording Changes from Ada 83

Implementation-defined pragmas may affect the run-time semantics of the program. This was always true in Ada 83 (since it was not explicitly forbidden by RM83), but it was not clear, because there was no definition of “executing” or “elaborating” a pragma.

Extensions to Ada 2005

\{AI05-0163-1\} Correction: Allow pragmas in place of a statement, even if there are no other statements in a \texttt{sequence_of_statements}.

\{AI05-0272-1\} Identifiers specific to a pragma can be reserved words.

\{AI05-0290-1\} Pragma arguments can be identified with \texttt{aspect_marks}; this allows \texttt{identifier'Class} in this context. As usual, this is only allowed if specifically allowed by a particular pragma.

Wording Changes from Ada 2005

\{AI05-0100-1\} Correction: Clarified where pragmas are (and are not) allowed.

Syntax

The forms of \texttt{List}, \texttt{Page}, and \texttt{Optimize} pragmas are as follows:

\texttt{pragma List(identifier);}  
\texttt{pragma Page;}  
\texttt{pragma Optimize(identifier);}  

[Other pragmas are defined throughout this International Standard, and are summarized in Annex L.]

Ramification: The language-defined pragmas are supported by every implementation, although “supporting” some of them (for example, Inline) requires nothing more than checking the arguments, since they act only as advice to the implementation.

Static Semantics

A \texttt{pragma} \texttt{List} takes one of the \texttt{identifiers} \texttt{On} or \texttt{Off} as the single argument. This pragma is allowed anywhere a \texttt{pragma} is allowed. It specifies that listing of the compilation is to be continued or suspended until a \texttt{List} \texttt{pragma} with the opposite argument is given within the same compilation. The \texttt{pragma} itself is always listed if the compiler is producing a listing.
A **pragma** Page is allowed anywhere a **pragma** is allowed. It specifies that the program text which follows the **pragma** should start on a new page (if the compiler is currently producing a listing).

A **pragma** Optimize takes one of the identifiers Time, Space, or Off as the single argument. This **pragma** is allowed anywhere a **pragma** is allowed, and it applies until the end of the immediately enclosing declarative region, or for a **pragma** at the place of a compilation unit, to the end of the compilation. It gives advice to the implementation as to whether time or space is the primary optimization criterion, or that optional optimizations should be turned off. [It is implementation defined how this advice is followed.]

**Implementation defined:** Effect of **pragma** Optimize.

**Discussion:** For example, a compiler might use Time vs. Space to control whether generic instantiations are implemented with a macro-expansion model, versus a shared-generic-body model.

We don't define what constitutes an “optimization” — in fact, it cannot be formally defined in the context of Ada. One compiler might call something an optional optimization, whereas another compiler might consider that same thing to be a normal part of code generation. Thus, the programmer cannot rely on this **pragma** having any particular portable effect on the generated code. Some compilers might even ignore the **pragma** altogether.

**Examples**

Examples of **pragmas**:

```
{AI95-00433-01} {AI05-0229-1} **pragma** List (Off); -- turn off listing generation
**pragma** Optimize (Off); -- turn off optional optimizations
**pragma** Pure (Rational Numbers); -- set categorization for package
**pragma** Assert (Exists (File_Name),
    Message => "Nonexistent file"); -- assert file exists
**pragma**-Inline (Set_Mask); -- generate code for Set_Mask inline
**pragma** Import (C, Put_Char, External_Name => "putchar"); -- import C putchar function
**pragma** Suppress (Range_Check, On => Index); -- turn off range checking on Index
```

**Extensions to Ada 83**

The **Optimize** **pragma** now allows the identifier Off to request that normal optimization be turned off.

An **Optimize** **pragma** may appear anywhere **pragmas** are allowed.

**Wording Changes from Ada 83**

We now describe the **pragmas** Page, List, and **Optimize** here, to act as examples, and to remove the normative material from Annex L, “Language-Defined **Pragmas**”, so it can be entirely an informative annex.

**Wording Changes from Ada 95**

{AI95-00433-01} Updated the example of named **pragma** parameters, because the second parameter of **pragma** Suppress is obsolescent.

**Wording Changes from Ada 2005**

{AI05-0229-1} Updated the example of **pragmas**, because both **pragmas** Inline and Import are obsolescent.
2.9 Reserved Words

This paragraph was deleted.

{AI95-00284-02} {AI95-00395-01} {AI05-0091-1} The following are the reserved words. Within a program, some or all of the letters of a reserved word may be in upper case, and one or more characters in category other_format may be inserted within or at the end of the reserved word. (ignoring upper/lower case distinctions):

Discussion: Reserved words have special meaning in the syntax. In addition, certain reserved words are used as attribute names.

The syntactic category identifier no longer allows reserved words. We have added the few reserved words that are legal explicitly to the syntax for attribute_reference. Allowing identifier to include reserved words has been a source of confusion for some users, and differs from the way they are treated in the C and Pascal language definitions.

 abort abs abstract accept access aliased all and array at begin body case constant declare delay delta digits do else end entry exception exit for function generic goto if in interface is limited loop mod not null new of or others out overriding package pragma private procedure protected raise range record rem renames return reverse select separate some subtype synchronized tagged task terminate then type until use when while with xor

NOTES

8 The reserved words appear in lower case boldface in this International Standard, except when used in the designator of an attribute (see 4.1.4). Lower case boldface is also used for a reserved word in a string_literal used as an operator_symbol. This is merely a convention — programs may be written in whatever typeface is desired and available.

Incompatibilities With Ada 83

The following words are not reserved in Ada 83, but are reserved in Ada 95: abstract, aliased, protected, requeue, tagged, until.

Wording Changes from Ada 83

3.b/3 The subclause entitled “Allowed Replacements of Characters” has been moved to Annex J, “Obsolescent Features”.

Incompatibilities With Ada 95

3.c/2 The following words are not reserved in Ada 95, but are reserved in Ada 2005: interface, overriding, synchronized. A special allowance is made for pragma Interface (see J.12). Uses of these words as identifiers will need to be changed, but we do not expect them to be common.
Wording Changes from Ada 95

{AI95-00395-01} The definition of upper case equivalence has been modified to allow identifiers using all of the characters of ISO 10646. This change has no effect on the character sequences that are reserved words, but does make some unusual sequences of characters illegal.

Incompatibilities With Ada 2005

{AI05-0091-1} **Correction:** Removed other_format characters from reserved words in order to be compatible with the latest Unicode recommendations. This change can only affect programs written for original Ada 2005, and there is little reason to put other_format characters into reserved words in the first place, so there should be very few such programs.

{AI05-0176-1} The following word is not reserved in Ada 2005, but is reserved in Ada 2012: **some.** Uses of this word as an identifier will need to be changed, but we do not expect them to be common.
3 Declarations and Types

This clause section describes the types in the language and the rules for declaring constants, variables, and named numbers.

3.1 Declarations

The language defines several kinds of named entities that are declared by declarations. The entity's name is defined by the declaration, usually by a defining_identifier, but sometimes by a defining_character_literal or defining_operator_symbol.

There are several forms of declaration. A basic_declaration is a form of declaration defined as follows.

Syntax

```
| type_declaration | subtype_declaration |
| object_declaration | number_declaration |
| subprogram_declaration | abstract_subprogram_declaration |
| null_procedure_declaration | expression_function_declaration |
| package_declaration | renaming_declaration |
| exception_declaration | generic_declaration |
| generic_instantiation |

defining_identifier ::= identifier
```

Static Semantics

A declaration is a language construct that associates a name with (a view of) an entity. A declaration may appear explicitly in the program text (an explicit declaration), or may be supposed to occur at a given place in the text as a consequence of the semantics of another construct (an implicit declaration).

Discussion: An implicit declaration generally declares a predefined or inherited operation associated with the definition of a type. This term is used primarily when allowing explicit declarations to override implicit declarations, as part of a type declaration.

Each of the following is defined to be a declaration: any basic_declaration; an enumeration_literal Specification; a discriminant Specification; a component_declaration; a loop_parameter_specification; an iterator_specification; a parameter_specification; a subprogram_body; an extended_return_object_declaration; an entry_declaration; an entry_index_specification; a choice_parameter_specification; a generic_formal_parameter_declaration. In addition, an extended_return_statement is a declaration of its defining_identifier.

Discussion: This list (when basic_declaration is expanded out) contains all syntactic categories that end in "_declaration" or "_specification", except for program_unit_specifications. Moreover, it contains subprogram_body. A subprogram_body is a declaration, whether or not it completes a previous declaration. This is a bit strange, subprogram_body is not part of the syntax of basic_declaration or library_unit_declaration. A renaming-as-body is considered a declaration. An accept_statement is not considered a declaration. Completions are sometimes declarations, and sometimes not.

All declarations contain a definition for a view of an entity. A view consists of an identification of the entity (the entity of the view), plus view-specific characteristics that affect the use of the entity through that view (such as mode of access to an object, formal parameter names and defaults for a subprogram, or
visibility to components of a type). In most cases, a declaration also contains the definition for the entity itself (a renaming_declaration is an example of a declaration that does not define a new entity, but instead defines a view of an existing entity (see 8.5)).

Glossary entry: A view of an entity reveals some or all of the properties of the entity. A single entity may have multiple views. (See Definition.)

Discussion: Most declarations define a view (of some entity) whose view-specific characteristics are unchanging for the life of the view. However, subtypes are somewhat unusual in that they inherit characteristics from whatever view of their type is currently visible. Hence, a subtype is not a view of a type; it is more of an indirect reference. By contrast, a private type provides a single, unchanging (partial) view of its full type.

This paragraph was deleted. Glossary entry: All declarations contain a definition for a view of an entity. A view consists of an identification of the entity (the entity of the view), plus view-specific characteristics that affect the use of the entity through that view (such as mode of access to an object, formal parameter names and defaults for a subprogram, or visibility to components of a type). In most cases, a declaration also contains the definition for the entity itself (a renaming_declaration is an example of a declaration that does not define a new entity, but instead defines a view of an existing entity (see 8.5)).

When it is clear from context, the term object is used in place of view of an object. Similarly, the terms type and subtype are used in place of view of a type and view of a subtype, respectively.

Discussion: Rules interpreted at compile time generally refer to views of entities, rather than the entities themselves. This is necessary to preserve privacy; characteristics that are not visible should not be used in compile-time rules. Thus, Static Semantics and Legality Rules generally implicitly have “view of”. Legality Rules that need to look into the private part are the exception to this interpretation.

On the other hand, run-time rules can work either way, so “view of” should not be assumed in Dynamic Semantics rules.

For each declaration, the language rules define a certain region of text called the scope of the declaration (see 8.2). Most declarations associate an identifier with a declared entity. Within its scope, and only there, there are places where it is possible to use the identifier to refer to the declaration, the view it defines, and the associated entity; these places are defined by the visibility rules (see 8.3). At such places the identifier is said to be a name of the entity (the direct_name or selector_name); the name is said to denote the declaration, the view, and the associated entity (see 8.6). The declaration is said to declare the name, the view, and in most cases, the entity itself.

As an alternative to an identifier, an enumeration literal can be declared with a character_l literal as its name (see 3.5.1), and a function can be declared with an operator_symbol as its name (see 6.1).

The syntax rules use the terms defining_identifier, defining_character_l literal, and defining_operator_symbol for the defining occurrence of a name; these are collectively called defining names. The terms direct_name and selector_name are used for usage occurrences of identifiers, character_literals, and operator_symbols. These are collectively called usage names.

To be honest: The terms identifier, character_l literal, and operator_symbol are used directly in contexts where the normal visibility rules do not apply (such as the identifier that appears after the end of a task_body). Analogous conventions apply to the use of designator, which is the collective term for identifier and operator_symbol.

Dynamic Semantics

The process by which a construct achieves its run-time effect is called execution. This process is also called elaboration for declarations and evaluation for expressions. One of the terms execution, elaboration, or evaluation is defined by this International Standard for each construct that has a run-time effect.

Glossary entry: The process by which a construct achieves its run-time effect is called execution. Execution of a declaration is also called elaboration. Execution of an expression is also called evaluation.
To be honest: The term elaboration is also used for the execution of certain constructs that are not declarations, and the term evaluation is used for the execution of certain constructs that are not expressions. For example, subtype indications are elaborated, and ranges are evaluated.

For bodies, execution and elaboration are both explicitly defined. When we refer specifically to the execution of a body, we mean the explicit definition of execution for that kind of body, not its elaboration.

Discussion: Technically, "the execution of a declaration" and "the elaboration of a declaration" are synonymous. We use the term "elaboration" of a construct when we know the construct is elaborable. When we are talking about more arbitrary constructs, we use the term "execution". For example, we use the term "erroneous execution", to refer to any erroneous execution, including erroneous elaboration or evaluation.

When we explicitly define evaluation or elaboration for a construct, we are implicitly defining execution of that construct.

We also use the term "execution" for things like statements, which are executable, but neither elaborable nor evaluable. We considered using the term "execution" only for nonelaborable, nonevaluable constructs, and defining the term "action" to mean what we have defined "execution" to mean. We rejected this idea because we thought three terms that mean the same thing was enough — four would be overkill. Thus, the term "action" is used only informally in the standard (except where it is defined as part of a larger term, such as "protected action").

Glossary entry: The process by which a declaration achieves its run-time effect is called elaboration. Elaboration is one of the forms of execution.

Glossary entry: The process by which an expression achieves its run-time effect is called evaluation. Evaluation is one of the forms of execution.

To be honest: A construct is elaborable if elaboration is defined for it. A construct is evaluable if evaluation is defined for it. A construct is executable if execution is defined for it.

Discussion: Don't confuse "elaborable" with "preelaborable" (defined in 10.2.1).

\{AI95-00114-01\} Evaluation of an elaboratable construct produces a result that is either a value, a denotation, or a range. The following are evaluable: expression; name prefix; range; entry_index_specification; entry_list_iterator; and possibly discrete_range. The last one is curious — RM83 uses the term “evaluation of a discrete_range,” but never defines it. One might presume that the evaluation of a discrete_range consists of the evaluation of the range or the subtype_indication, depending on what it is. But subtype_indications are not evaluated; they are elaborated.

Intuitively, an executable construct is one that has a defined run-time effect (which may be null). Since execution includes elaboration and evaluation as special cases, all elaborable and all evaluable constructs are also executable. Hence, most constructs in Ada are executable. An important exception is that the constructs inside a generic unit are not executable directly, but rather are used as a template for (generally) executable constructs in instances of the generic.

NOTES
1 At compile time, the declaration of an entity declares the entity. At run time, the elaboration of the declaration creates the entity.

Ramification: Syntactic categories for declarations are named either entity_declaration (if they include a trailing semicolon) or entity_specification (if not).

The various kinds of named entities that can be declared are as follows: an object (including components and parameters), a named number, a type (the name always refers to its first subtype), a subtype, a subprogram (including enumeration literals and operators), a single entry, an entry family, a package, a protected or task unit (which corresponds to either a type or a single object), an exception, a generic unit, a label, and the name of a statement.

Identifiers are also associated with names of pragmas, arguments to pragmas, and with attributes, but these are not user-definable.

Wording Changes from Ada 83

The syntax rule for defining_identifier is new. It is used for the defining occurrence of an identifier. Usage occurrences use the direct_name or selector_name syntactic categories. Each occurrence of an identifier (or simple_name), character_literal, or operator_symbol in the Ada 83 syntax rules is handled as follows in Ada 95:

- It becomes a defining_identifier, defining_character_literal, or defining_operator_symbol (or some syntactic category composed of these), to indicate a defining occurrence;
- \{AI05-0299-1\} It becomes a direct_name, in usage occurrences where the usage is required (in ClauseSection 8) to be directly visible;
- \{AI05-0299-1\} It becomes a selector_name, in usage occurrences where the usage is required (in ClauseSection 8) to be visible but not necessarily directly visible;
The types of a given class share a set of primitive operations. Classes are 

There exist several 

The defining occurrence of a statement name is in its implicit declaration, not where it appears in the program text. Considering the statement name itself to be the defining occurrence would complicate the visibility rules.

The phrase “visible by selection” is not used in Ada 95. It is subsumed by simply “visible” and the Name Resolution Rules for selector_names.

We use the term “declaration” to cover _specifications that declare (views of) objects, such as parameter_specifications. In Ada 83, these are referred to as a “form of declaration,” but it is not entirely clear that they are considered simply “declarations.”

RM83 contains an incomplete definition of "elaborated" in this subclause: it defines "elaborated" for declarations, declarative_parts, declarative_items and compilation_units, but "elaboration" is defined elsewhere for various other constructs. To make matters worse, Ada 95 has a different set of elaborable constructs. Instead of correcting the list, it is more maintainable to refer to the term "elaborable," which is defined in a distributed manner.

We make it clearer that the term "execution" covers elaboration and evaluation as special cases. This was implied in RM83. For example, "erroneous execution" can include any execution, and RM83-9.4(3) has, "The task designated by the master whose execution creates the task object;" the elaboration of the master's declarative_part is doing the task creation.

Wording Changes from Ada 95

Added extended_return_statement to the list of declarations.

Added null procedures (see 6.7) to the syntax.

Wording Changes from Ada 2005

Added expression functions (see 6.8) to the syntax.

3.2 Types and Subtypes

A type is characterized by a set of values, and a set of primitive operations which implement the fundamental aspects of its semantics. An object of a given type is a run-time entity that contains (has) a value of the type.

Glossary entry: Each object has a type. A type has an associated set of values, and a set of primitive operations which implement the fundamental aspects of its semantics. Types are grouped into categories of types. Most language-defined categories of types are also classes of types. Most of the fundamental operations of a type are implemented by the implementation of the type in the language, and the language defines the interface to these operations. The types of a given class share a set of primitive operations. Classes are closed under derivation; that is, if a type is in a class, then all of its derivatives are in that class.

Glossary entry: A subtype is a type together with optional constraints, null exclusions, and predicatessa a constraint or null exclusion, which constrains the values of the subtype to satisfy a certain condition. The values of a subtype are a subset of the values of its type.

Types are grouped into categories of types, reflecting the similarity of their values and primitive operations. There exist several language-defined categories of types (see NOTES below), reflecting the similarity of their values and primitive operations. [Most categories of
types form classes of types.] Elementary types are those whose values are logically indivisible; composite types are those whose values are composed of component values.

**Proof:** [AI95-00442-01] The formal definition of category and class is found in 3.4.

**Glossary entry:** A class is a set of types that is closed under derivation, which means that if a given type is in the class, then all types derived from that type are also in the class. The set of types of a class share common properties, such as their primitive operations.

**Glossary entry:** A category of types is a set of types with one or more common properties, such as primitive operations. A category of types that is closed under derivation is also known as a class.

**Glossary entry:** An elementary type does not have components.

**Glossary entry:** A composite type may have components.

**Glossary entry:** A scalar type is either a discrete type or a real type.

**Glossary entry:** An access type has values that designate aliased objects. Access types correspond to “pointer types” or “reference types” in some other languages.

**Glossary entry:** A discrete type is either an integer type or an enumeration type. Discrete types may be used, for example, in case statements and as array indices.

**Glossary entry:** A real type has values that are approximations of the real numbers. Floating point and fixed point types are real types.

**Glossary entry:** Integer types comprise the signed integer types and the modular types. A signed integer type has a base range that includes both positive and negative numbers, and has operations that may raise an exception when the result is outside the base range. A modular type has a base range whose lower bound is zero, and has operations with “wraparound” semantics. Modular types subsume what are called “unsigned types” in some other languages.

**Glossary entry:** An enumeration type is defined by an enumeration of its values, which may be named by identifiers or character literals.

**Glossary entry:** A character type is an enumeration type whose values include characters.

**Glossary entry:** A record type is a composite type consisting of zero or more named components, possibly of different types.

**Glossary entry:** A record extension is a type that extends another type by adding additional components.

**Glossary entry:** An array type is a composite type whose components are all of the same type. Components are selected by indexing.

**Glossary entry:** A task type is a composite type used to represent active entities which may execute concurrently and which can communicate via queued task entries with other tasks. The top-level task of a partition is called the environment task.

**Glossary entry:** A protected type is a composite type whose components are accessible only through one of its protected operations which synchronizes protected from concurrent access by multiple tasks.

**Glossary entry:** A private type gives a partial view of a type that reveals only some of its properties. The remaining properties are provided by the full view given elsewhere. Private types can be used for defining abstractions that hide unnecessary details hidden from their clients.

**Glossary entry:** A private extension is a type that extends another type, with the additional properties of a record extension, except that the components of the extension part are hidden from its clients.

**Glossary entry:** An incomplete type gives a partial view of a type that reveals only some of its properties. The remaining properties are provided by the full view given elsewhere. Incomplete types can be used for defining recursive data structures.

The elementary types are the scalar types (discrete and real) and the access types (whose values provide access to objects or subprograms). Discrete types are either integer types or are defined by enumeration of their values (enumeration types). Real types are either floating point types or fixed point types.

**AI95-00251-01** {AI95-00326-01} The composite types are the record types, record extensions, array types, interface types, task types, and protected types. A private type or private extension represents a partial view (see 7.3) of a type, providing support for data abstraction. A partial view is a composite type.

This paragraph was deleted. To be honest...
types (other than array types) can have discriminations. Similarly, the set of all private types do not form a class (because tagged private types can have record extensions), though the set of untagged private types do. Nevertheless, the set of untagged private types is not particularly “interesting” — more interesting is the set of all nonlimited types, since that is what a generic formal (nonlimited) private type matches.

4.1/2 \{AI95-00326-01\} There can be multiple views of a type with varying sets of operations. [An incomplete type represents an incomplete view (see 3.10.1) of a type with a very restricted usage, providing support for recursive data structures. A private type or private extension represents a partial view (see 7.3) of a type, providing support for data abstraction. The full view (see 3.2.1) of a type represents its complete definition.] An incomplete or partial view is considered a composite type, even if the full view is not.

4.b/3 \textbf{Proof:} \{AI05-0299-1\} The real definitions of the views are in the referenced subclauses.

5/2 \{AI95-00326-01\} Certain composite types (and partial views thereof) have special components called discriminants whose values affect the presence, constraints, or initialization of other components. Discriminants can be thought of as parameters of the type.

6/2 \{AI95-00336-01\} The term subcomponent is used in this International Standard in place of the term component to indicate either a component, or a component of another subcomponent. Where other subcomponents are excluded, the term component is used instead. Similarly, a part of an object or value is used to mean the whole object or value, or any set of its subcomponents. The terms component, subcomponent, and part are also applied to a type meaning the component, subcomponent, or part of objects and values of the type.

6.a \textbf{Discussion:} The definition of “part” here is designed to simplify rules elsewhere. By design, the intuitive meaning of “part” will convey the correct result to the casual reader, while this formalistic definition will answer the concern of the compiler-writer.

6.b We use the term “part” when talking about the parent part, ancestor part, or extension part of a type extension. In contexts such as these, the part might represent an empty set of subcomponents (e.g. in a null record extension, or a nonnull extension of a null record). We also use “part” when specifying rules such as those that apply to an object with a “controlled part” meaning that it applies if the object as a whole is controlled, or any subcomponent is.

7/2 \{AI95-00231-01\} The set of possible values for an object of a given type can be subjected to a condition that is called a constraint (the case of a null constraint that specifies no restriction is also included); the rules for which values satisfy a given kind of constraint are given in 3.5 for range constraints, 3.6.1 for index constraints, and 3.7.1 for discriminant constraints. The set of possible values for an object of an access type can also be subjected to a condition that excludes the null value (see 3.10).

8/2 \{AI95-00231-01\} \{AI95-00415-01\} A subtype of a given type is a combination of the type, a constraint on values of the type, and certain attributes specific to the subtype. The given type is called the type of the subtype of the subtype. Similarly, the associated constraint is called the constraint of the subtype of the subtype. The set of values of a subtype consists of the values of its type that satisfy its constraint and any exclusion of the null value. Such values belong to the subtype.

8.a \textbf{Discussion:} We make a strong distinction between a type and its subtypes. In particular, a type is not a subtype of itself. There is no constraint associated with a type (not even a null one), and type-related attributes are distinct from subtype-specific attributes.

8.b \textbf{Discussion:} We no longer use the term “base type.” All types were "base types" anyway in Ada 83, so the term was redundant, and occasionally confusing. In the RM95 we say simply "the type of the subtype" instead of "the base type of the subtype."

8.c \textbf{Ramification:} The value subset for a subtype might be empty, and need not be a proper subset.

8.d/2 \textbf{To be honest:} \{AI95-00442-01\} Any name of a category class of types (such as “discrete” or “real”) or other category of types (such as “limited” or “incomplete”) is also used to qualify its subtypes, as well as its objects, values, declarations, and definitions, such as an “integer type declaration” or an “integer value.” In addition, if a term such as “parent subtype” or “index subtype” is defined, then the corresponding term for the type of the subtype is “parent type” or “index type.”

8.e \textbf{Discussion:} We use these corresponding terms without explicitly defining them, when the meaning is obvious.
A subtype is called an un
\textit{constrained} subtype if its type has unknown discriminants, or if its type allows range, index, or discriminant constraints, but the subtype does not impose such a constraint; otherwise, the subtype is called a \textit{constrained} subtype (since it has no unconstrained characteristics).

\textbf{Discussion:} In an earlier version of Ada 9X, "constrained" meant "has a nonnull constraint." However, we changed to this definition since we kept having to special case composite non-array/nondiscriminated types. It also corresponds better to the (now obsolescent) attribute "Constrained.

For scalar types, “constrained” means “has a nonnull constraint”. For composite types, in implementation terms, “constrained” means that the size of all objects of the subtype is the same, assuming a typical implementation model.

Class-wide subtypes are always unconstrained.

\textbf{NOTES}
\item Any set of types can be called a “category” of types, and any set of types that is closed under derivation (see 3.4) can be called a “class” of types. However, only certain categories and classes are used in the description of the rules of the language — generally those that have their own particular set of primitive operations (see 3.2.3), or that correspond to a set of types that are matched by a given kind of generic formal type (see 12.5). The following are examples of “interesting” language-defined classes: elementary, scalar, discrete, enumeration, character, boolean, integer, signed integer, modular, real, floating point, fixed point, ordinary fixed point, decimal fixed point, numeric, access, access-to-object, access-to-subprogram, composite, array, string, (untagged) record, tagged, task, protected, nonlimited. Special syntax is provided to define types in each of these classes. In addition to these classes, the following are examples of “interesting” language-defined categories: abstract, incomplete, interface, limited, private, record.

\textbf{Discussion:} A value is a run-time entity with a given type which can be assigned to an object of an appropriate subtype of the type. An \textit{operation} is a program entity that operates on zero or more operands to produce an effect, or yield a result, or both.

\textbf{Ramiﬁcation:} Note that a type's category (and class) depends on the place of the reference — a private type is composite outside and possibly elementary inside. It's really the \textit{view} that is elementary or composite. Note that although private types are composite, there are some properties that depend on the corresponding full view — for example, parameter passing modes, and the constraint checks that apply in various places.

\item Every property of types forms a category, but not every property of types represents a class. For example, the set of all abstract types does not form a class, because this set is not closed under derivation. Similarly, the set of all interface types does not form a class.

\item The set of limited types does not form a class (since nonlimited types can inherit from limited interfaces), but the set of nonlimited types does. The set of tagged record types and the set of tagged private types do not form a class (because each of them can be extended to create a type of the other category); that implies that the set of record types and the set of private types also do not form a class (even though untagged record types and untagged private types do form a class). In all of these cases, we can talk about the category of the type; for instance, we can talk about the "category of limited types" forms a class in the sense that it is closed under derivation, but the more interesting class, from the point of generic formal type matching, is the set of all types, limited and nonlimited, since that is what matches a generic formal "limited" private type. Note also that a limited type can "become nonlimited" under certain circumstances, which makes "limited" somewhat problematic as a class of types.

\item Normatively, the language-defined classes are those that are defined to be inherited on derivation by 3.4; other properties either aren't interesting or form categories, not classes.

\item These language-defined categories are organized like this:

\begin{verbatim}
all types
  elementary
    scalar
      discrete
        enumeration
          character
            boolean
              other enumeration
                integer
                  signed integer
                    modular integer
                      real
                        floating point
                          fixed point
                            ordinary fixed point
                              decimal fixed point
                                access
\end{verbatim}
There are other categories, such as “numeric” and “discriminated nonlimited”, which represent other categorization dimensions, but do not fit into the above strictly hierarchical picture.

Discussion: There is also true for some categories mentioned in the chart. The category “task” includes both untagged tasks and tagged tasks. Similarly for “protected”, “limited” and “nonlimited” (note that limited and nonlimited are not shown for untagged composite types).

Wording Changes from Ada 83

This subclause and its subclauses now precede the clause and subclauses on objects and named numbers, to cut down on the number of forward references.

We have dropped the term “base type” in favor of simply “type” (all types in Ada 83 were “base types” so it wasn’t clear when it was appropriate/necessary to say “base type”). Given a subtype S of a type T, we call T the “type of the subtype S.”

Wording Changes from Ada 95

Added a mention of null exclusions when we’re talking about constraints (these are not constraints, but they are similar).

Defined an interface type to be a composite type.

Revised the wording so that it is clear that an incomplete view is similar to a partial view in terms of the language.

Added a definition of component of a type, subcomponent of a type, and part of a type. These are commonly used in the standard, but they were not previously defined.

Reworded most of this subclause to use category rather than class, since so many interesting properties are not, strictly speaking, classes. Moreover, there was no normative description of exactly which properties formed classes, and which did not. The real definition of class, along with a list of properties, is now in 3.4.

### 3.2.1 Type Declarations

A type declaration declares a type and its first subtype.

#### Syntax

```
type_declaration ::= full_type_declaration
| incomplete_type_declaration
| private_type_declaration
| private_extension_declaration
```
A given type shall not have a subcomponent whose type is the given type itself.

**Static Semantics**

The defining_identifier of a type_declaration denotes the first subtype of the type. The known_discriminant_part, if any, defines the discriminants of the type (see 3.7, “Discriminants”). The remainder of the type_declaration defines the remaining characteristics of (the view of) the type.

A type defined by a type_declaration is a named type; such a type has one or more nameable subtypes. Certain other forms of declaration also include type definitions as part of the declaration for an object (including a parameter or a discriminant). The type defined by such a declaration is anonymous — it has no nameable subtypes. For explanatory purposes, this International Standard sometimes refers to an anonymous type by a pseudo-name, written in italics, and uses such pseudo-names at places where the syntax normally requires an identifier. For a named type whose first subtype is T, this International Standard sometimes refers to the type of T as simply “the type T”.

**Ramification:** A type that is declared by a full_type_declaration, or an anonymous type that is defined by an access_definition or as part of declaring an object of the type, is called a full type. The declaration of a full type also declares the full view of the type. The type_definition, task_definition, protected_definition, or access_definition that defines a full type is called a full type definition. [Types declared by other forms of type_declaration are not separate types; they are partial or incomplete views of some full type.]
environment”. We do not use this term to refer to library packages other than Standard. For example Text_IO is a language-defined package, not a predefined package, and Text_IO.Put_Line is not a predefined operation.

**Dynamic Semantics**

The elaboration of a *full_type_declaration* consists of the elaboration of the full type definition. Each elaboration of a full type definition creates a distinct type and its first subtype.

**Reason:** The creation is associated with the type *definition*, rather than the type *declaration*, because there are types that are created by full type definitions that are not immediately contained within a type declaration (e.g. an array object declaration, a singleton task declaration, etc.).

**Ramification:** Any implicit declarations that occur immediately following the full type definition are elaborated where they (implicitly) occur.

**Examples of type definitions:**

```
(White, Red, Yellow, Green, Blue, Brown, Black)
range 1 .. 72
array(1 .. 10) of Integer
```

**Examples of type declarations:**

```
type Color is (White, Red, Yellow, Green, Blue, Brown, Black);
type Column is range 1 .. 72;
type Table is array(1 .. 10) of Integer;
```

**Notes**

3 Each of the above examples declares a named type. The identifier given denotes the first subtype of the type. Other named subtypes of the type can be declared with *subtype_declarations* (see 3.2.2). Although names do not directly denote types, a phrase like “the type Column” is sometimes used in this International Standard to refer to the type of Column, where Column denotes the first subtype of the type. For an example of the definition of an anonymous type, see the declaration of the array Color_Table in 3.3.1; its type is anonymous — it has no nameable subtypes.

**Wording Changes from Ada 83**

We have generalized the concept of first-named subtype (now called simply “first subtype”) to cover all kinds of types, for uniformity of description elsewhere. RM83 defined first-named subtype in Section 13. We define first subtype here, because it is now a more fundamental concept. We renamed the term, because in Ada 95 some first subtypes have no name.

**Wording Changes from Ada 95**

Added wording so that anonymous access types are always full types, even if they appear in renames.

Added interface types (see 3.9.4) to the syntax.

Added a definition of full view, so that all types have a well-defined full view.

**Extensions to Ada 2005**

An optional *aspect_specification* can be used in a *full_type_declaration*. This is described in 13.1.1.

### 3.2.2 Subtype Declarations

A *subtype_declaration* declares a subtype of some previously declared type, as defined by a *subtype_indication*.
Syntax

{AI05-0183-1} subtype declaration ::= 
  subtype defining_identifier is subtype_indication 
  [aspect_specification];

{AI95-00231-01} subtype_indication ::= [null_exclusion] subtype_mark [constraint]

subtype_mark ::= subtype_name

Ramification: Note that name includes attribute_reference; thus, S'Base can be used as a subtype_mark.
Reason: We considered changing subtype_mark to subtype_name. However, existing users are used to the word "mark," so we're keeping it.

criterion ::= scalar_constraint | composite_constraint

criterion ::= range_constraint | digits_constraint | delta_constraint

Dynamic Semantics

The elaboration of a subtype_declaration consists of the elaboration of the subtype_indication. The elaboration of a subtype_indication creates a new subtype. If the subtype_indication does not include a constraint, the new subtype has the same (possibly null) constraint as that denoted by the subtype_mark. The elaboration of a subtype_indication that includes a constraint proceeds as follows:

• The constraint is first elaborated.

• A check is then made that the criterion is compatible with the subtype denoted by the subtype_mark.

Ramification: The checks associated with constraint compatibility are all Range_Checks. Discriminant_Checks and Index_Checks are associated only with checks that a value satisfies a constraint.

The condition imposed by a criterion is the condition obtained after elaboration of the criterion. The rules defining compatibility are given for each form of criterion in the appropriate subclause. These rules are such that if a criterion is compatible with a subtype, then the condition imposed by the criterion cannot contradict any condition already imposed by the subtype on its values. The exception Constraint_Error is raised if any check of compatibility fails.

To be honest: The condition imposed by a criterion is named after it — a range_constraint imposes a range constraint, etc.

Ramification: A range_constraint causes freezing of its type. Other constraints do not.

NOTES
4 A scalar_constraint may be applied to a subtype of an appropriate scalar type (see 3.5, 3.5.9, and J.3), even if the subtype is already constrained. On the other hand, a composite_constraint may be applied to a composite subtype (or an access-to-composite subtype) only if the composite subtype is unconstrained (see 3.6.1 and 3.7.1).
Examples of subtype declarations:

```ada
subtype Rainbow is Color range Red .. Blue; -- see 3.2.1
subtype Red_Blue is Rainbow;
subtype Int is Integer;
subtype Small_Int is Integer range -10 .. 10;
subtype Up_To_K is Column range 1 .. K; -- see 3.2.1
subtype Square is Matrix(1 .. 10, 1 .. 10); -- see 3.6
subtype Male is Person(Sex => M); -- see 3.10.1
subtype Binop_Ref is not null Binop_Ptr; -- see 3.10
```

Incompatibilities With Ada 83

In Ada 95, all range_constraints cause freezing of their type. Hence, a type-related representation item for a scalar type has to precede any range_constraints whose type is the scalar type.

Wording Changes from Ada 83

Subtype_marks allow only subtype names now, since types are never directly named. There is no need for RM83-3.3.2(3), which says a subtype_mark can denote both the type and the subtype; in Ada 95, you denote an unconstrained (base) subtype if you want, but never the type.

The syntactic category type_mark is now called subtype_mark, since it always denotes a subtype.

Extensions to Ada 95

An optional null_exclusion can be used in a subtype_indication. This is described in 3.10.

Extensions to Ada 2005

An optional aspect_specification can be used in a subtype_declaration. This is described in 13.1.1.

3.2.3 Classification of Operations

Static Semantics

An operation operates on a type T if it yields a value of type T, if it has an operand whose expected type (see 8.6) is T, or if it has an access parameter or access_result_type (see 6.1) designating T. A predefined operator, or other language-defined operation such as assignment or a membership test, that operates on a type, is called a predefined operation of the type. The primitive operations of a type are the predefined operations of the type, plus any user-defined primitive subprograms.

Glossary entry: The primitive operations of a type are the operations (such as subprograms) declared together with the type declaration. They are inherited by other types in the same class of types. For a tagged type, the primitive subprograms are dispatching subprograms, providing run-time polymorphism. A dispatching subprogram may be called with statically tagged operands, in which case the subprogram body invoked is determined at compile time. Alternatively, a dispatching subprogram may be called using a dispatching call, in which case the subprogram body invoked is determined at run time.

To be honest: Protected subprograms are not considered to be “primitive subprograms,” even though they are subprograms, and they are inherited by derived types.

Discussion: We use the term “primitive subprogram” in most of the rest of the manual. The term “primitive operation” is used mostly in conceptual discussions.

The primitive subprograms of a specific type are defined as follows:

- The predefined operators of the type (see 4.5);
- For a derived type, the inherited (see 3.4) user-defined subprograms;
- For an enumeration type, the enumeration literals (which are considered parameterless functions — see 3.5.1);
• For a specific type declared immediately within a `package_specification`, any subprograms (in addition to the enumeration literals) that are explicitly declared immediately within the same `package_specification` and that operate on the type;

• `{AI05-0128-1}` For a specific type with an explicitly declared primitive `"="` operator whose result type is Boolean, the corresponding `"=/"` operator (see 6.6);

• `{AI95-00200-01}` For a nonformal type, any subprograms not covered above [that are explicitly declared immediately within the same declarative region as the type] and that override (see 8.3) other implicitly declared subprograms of the type.

Discussion: In Ada 83, only subprograms declared in the visible part were “primitive” (i.e. derivable). In Ada 95, mostly because of child library units, we include all operations declared in the private part as well, and all operations that override implicit declarations.

Ramification: It is possible for a subprogram to be primitive for more than one type, though it is illegal for a subprogram to be primitive for more than one tagged type. See 3.9.

Discussion: The order of the implicit declarations when there are both predefined operators and inherited subprograms is described in 3.4, “Derived Types and Classes”.

Ramification: `{AI95-00200-01}` Subprograms declared in a generic package specification are never primitive for a formal type, even if they happen to override an operation of the formal type. This includes formal subprograms, which are never primitive operations (that's true even for an abstract formal subprogram).

A primitive subprogram whose designator is an `operator_symbol` is called a `primitive operator`.

Incompatibilities With Ada 83

The attribute S'Base is no longer defined for nonscalar subtypes. Since this was only permitted as the prefix of another attribute, and there are no interesting nonscalar attributes defined for an unconstrained composite or access subtype, this should not affect any existing programs.

Extensions to Ada 83

The primitive subprograms (derivable subprograms) include subprograms declared in the private part of a package specification as well, and those that override implicitly declared subprograms, even if declared in a body.

Wording Changes From Ada 83

We have dropped the confusing term `operation of a type` in favor of the more useful `primitive operation of a type` and the phrase `operates on a type`.

The description of S'Base has been moved to 3.5, “Scalar Types” because it is now defined only for scalar types.

Wording Changes From Ada 95

{AI95-00200-01} Clarified that a formal subprogram that happens to override a primitive operation of a formal type is not a primitive operation (and thus not a dispatching operation) of the formal type.

{AI95-00416-01} Added wording to include access result types in the kinds of operations that operate on a type T.

Wording Changes From Ada 2005

{AI05-0128-1} Correction: The implicitly declared `"=/="` for a primitive `"="` operator is also primitive; this makes it eligible to be made visible by a `use type` clause.

3.2.4 Subtype Predicates

{AI05-0153-3} {AI05-0269-1} {AI05-0299-1} The language-defined predicate aspects `Static_Predicate` and `Dynamic_Predicate` may be used to define properties of subtypes. A `predicate specification` is an `aspect_specification` for one of the two predicate aspects. General rules for aspects and `aspect_specifications` are found in Clause Section 13 (13.1 and 13.1.1 respectively).

Aspect Description for `Static_Predicate`: Condition that must hold true for objects of a given subtype; the subtype may be static.
Aspect Description for Dynamic Predicate: Condition that must hold true for objects of a given subtype; the subtype is not static.

Name Resolution Rules

{AI05-0153-3} The expected type for a predicate aspect expression is any boolean type.

Static Semantics

{AI05-0153-3} A predicate specification may be given on a type declaration or a subtype declaration, and applies to the declared subtype. In addition, predicate specifications apply to certain other subtypes:

- For a (first) subtype defined by a derived type declaration, the predicates of the parent subtype and the progenitor subtypes apply.
- For a subtype created by a subtype indication, the predicate of the subtype denoted by the subtype_mark applies.

{AI05-0153-3} The predicate of a subtype consists of all predicate specifications that apply, and-ed together; if no predicate specifications apply, the predicate is True ([in particular, the predicate of a base subtype is True]).

{AI05-0290-1} Predicate checks are defined to be enabled or disabled for a given subtype as follows:

- If a subtype is declared by a type declaration or subtype declaration that includes a predicate specification, then:
  - if performing checks is required by the Static Predicate assertion policy (see 11.4.2) and the declaration includes a Static Predicate specification, then predicate checks are enabled for the subtype;
  - if performing checks is required by the Dynamic Predicate assertion policy (see 11.4.2) and the declaration includes a Dynamic Predicate specification, then predicate checks are enabled for the subtype;
  - otherwise, predicate checks are disabled for the subtype[, regardless of whether predicate checking is enabled for any other subtypes mentioned in the declaration];
- If a subtype is defined by a derived type declaration that does not include a predicate specification, then predicate checks are enabled for the subtype if and only if predicate checks are enabled for at least one of the parent subtype and the progenitor subtypes;
- If a subtype is created by a subtype indication other than in one of the previous cases, then predicate checks are enabled for the subtype if and only if predicate checks are enabled for the subtype denoted by the subtype_mark;
- Otherwise, predicate checks are disabled for the given subtype.

Discussion: In this case, no predicate specifications can apply to the subtype and so it doesn't typically matter whether predicate checks are enabled. This rule does make a difference, however, when determining whether predicate checks are enabled for another type when this type is one of multiple progenitors. See the “derived type declaration” wording above.

Even when predicate checks are disabled, a predicate can affect various Legality Rules, the results of membership tests, the items in a for loop, and the result of the Valid attribute.

Legality Rules

{AI05-0153-3} {AI05-0269-1} The expression of a Static Predicate specification shall be predicate-static; that is, one of the following:

- a static expression;
- a membership test whose simple expression is the current instance, and whose membership_choice_list meets the requirements for a static membership test (see 4.9);
• a case expression whose selecting expression is the current instance, and whose dependent expressions are static expressions;

• a call to a predefined equality or ordering operator, where one operand is the current instance, and the other is a static expression;

• \{AI05-0262-1\} a call to a predefined boolean logical operator, where each operand is predicate-static;

• \{AI05-0269-1\} a short-circuit control form where both operands are predicate-static; or

• a parenthesized predicate-static expression.

\{AI05-0262-1\} A predicate shall not be specified for an incomplete subtype.

Reason: The expression of such a predicate could not depend on the properties of the value of the type (since it doesn’t have any), so it is useless and we don’t want to require the added complexity needed to support it.

\{AI05-0287-1\} If a predicate applies to a subtype, then that predicate shall not mention any other subtype to which the same predicate applies.

Reason: This is intended to prevent recursive predicates, which cause definitional problems for static predicates. Inside of the predicate, the subtype name refers to the current instance of the subtype, which is an object, so a direct use of the subtype name cannot be recursive. But other subtypes naming the same type might:

```ada
type Really_Ugly is private;
private
  subtype Ugly is Really_Ugly;
  type Really_Ugly is new Integer
  with Static_Predicate => Really_Ugly not in Ugly; -- Illegal!
```

\{AI05-0153-3\} An index subtype, discrete range of an index constraint or slice, or a discrete subtype definition of a constrained array definition, entry declaration, or entry index specification shall not denote a subtype to which predicate specifications apply.

\{AI05-0153-3\} \{AI05-0262-1\} \{AI05-0287-1\} The discrete subtype definition of a loop parameter specification shall not denote a nonstatic subtype to which predicate specifications apply or any subtype to which Dynamic_Predicate specifications apply.

\{AI05-0153-3\} \{AI05-0262-1\} The discrete choice of a named array aggregate shall not denote a nonstatic subtype to which predicate specifications apply.

Reason: \{AI05-0262-1\} This rule prevents noncontiguous dynamically bounded array aggregates, which could be expensive to check for. (Array aggregates have rules to prevent problems with static subtypes.) We define this rule here so that the runtime generic body check applies.

\{AI05-0262-1\} In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

Dynamic Semantics

\{AI05-0153-3\} \{AI05-0290-1\} If predicate checks are enabled for a given subtype, then:

[On every subtype conversion, the predicate of the target subtype is evaluated, and a check is performed that the predicate is True. This includes all parameter passing, except for certain parameters passed by reference, which are covered by the following rule:] After normal completion and leaving of a subprogram, for each in out or out parameter that is passed by
reference, the predicate of the subtype of the actual is evaluated, and a check is performed that the predicate is True. For an object created by an \texttt{object\_declaration} with no explicit initialization \texttt{expression}, or by an uninitialized \texttt{allocator}, if any subcomponents have \texttt{default\_expressions}, the predicate of the nominal subtype of the created object is evaluated, and a check is performed that the predicate is True. \texttt{Assertions.Assertion_Error} is raised if any of these checks fail.

\textbf{Ramification:} Predicates are not evaluated at the point of the (subtype) declaration.

\textbf{Implementation Note:} Static Predicate checks can be removed even in the presence of potentially invalid values, just as constraint checks can be removed.

\texttt{AI05-0262-1}\ A value satisfies a predicate if the predicate is True for that value.

\texttt{AI05-0153-3}\ \texttt{AI05-0276-1}\ If any of the above Legality Rules is violated in an instance of a generic unit, \texttt{Program\_Error} is raised at the point of the violation.

\textbf{Discussion:} This is the usual way around the contract model; this applies even in instance bodies. Note that errors in instance specifications will be detected at compile-time by the "re-check" of the specification, only errors in the body should raise \texttt{Program\_Error}.

\section{Objects and Named Numbers}

\texttt{AI05-0153-3}\ \texttt{AI05-0262-1}\ \texttt{AI05-0276-1}\ \texttt{AI05-0290-1}\ Predicate aspects are new in Ada 2012.

\begin{quote}

\texttt{AI05-0153-3}\ \texttt{AI05-0262-1}\ \texttt{AI05-0276-1}\ \texttt{AI05-0290-1}\ Predicate aspects are new in Ada 2012.

\end{quote}

\section{3.3 Objects and Named Numbers}

{[}Objects are created at run time and contain a value of a given type. An object can be created and initialized as part of elaborating a declaration, evaluating an \texttt{allocator}, \texttt{aggregate}, or \texttt{function\_call}, or passing a parameter by copy. Prior to reclaiming the storage for an object, it is finalized if necessary (see 7.6.1).{]}\]

\textbf{Static Semantics}

All of the following are objects:

\begin{itemize}
  \item the entity declared by an \texttt{object\_declaration};
  \item a formal parameter of a subprogram, entry, or generic subprogram;
  \item a generic formal object;
  \item a loop parameter;
  \item a choice parameter of an \texttt{exception\_handler};
  \item an entry index of an \texttt{entry\_body};
  \item the result of dereferencing an access-to-object value (see 4.1);
  \item the \texttt{return\_object} of a \texttt{function} created as the result of evaluating a \texttt{function\_call} (or the equivalent operator invocation—see 6.6);
  \item the result of evaluating an \texttt{aggregate};
\end{itemize}
• \{AI05-0003-1\} a qualified_expression whose operand denotes an object;
• a component, slice, or view conversion of another object.

\{AI05-0054-2\} An object is either a constant object or a variable object. The value of a constant object cannot be changed between its initialization and its finalization, whereas the value of a variable object can be changed. Similarly, a view of an object is either a constant or a variable. All views of a constant elementary object are constant. All views of a constant composite object are constant, except for parts that are of controlled or immutably limited types; variable views of those parts and their subcomponents may exist. In this sense, objects of controlled and immutably limited types are inherently mutable. A constant view of a variable object cannot be used to modify its value—the value of the variable. The terms constant and variable by themselves refer to constant and variable views of objects.

The value of an object is read when the value of any part of the object is evaluated, or when the value of an enclosing object is evaluated. The value of a variable is updated when an assignment is performed to any part of the variable, or when an assignment is performed to an enclosing object.

Ramification: Reading and updating are intended to include read/write references of any kind, even if they are not associated with the evaluation of a particular construct. Consider, for example, the expression “X.all(F)”, where X is an access-to-array object, and F is a function. The implementation is allowed to first evaluate “X.all” and then F. Finally, a read is performed to get the value of the Fth component of the array. Note that the array is not necessarily read as part of the evaluation of “X.all”. This is important, because if F were to free X using Unchecked_Deallocation, we want the execution of the final read to be erroneous.

Whether a view of an object is constant or variable is determined by the definition of the view. The following (and no others) represent constants:

• an object declared by an object_declaration with the reserved word constant;

  To be honest: \{AI95-00385-01\} We mean the word constant as defined by the grammar for object_declaration, not some random word constant. Thus,

  \begin{verbatim}
  X : access constant T;
  \end{verbatim}

  is not a constant.

• a formal parameter or generic formal object of mode in;

• a discriminant;

\{AI05-0262-1\} a loop parameter unless specified to be a variable for a generalized loop (see 5.5.2);

\{AI05-0262-1\} a loop parameter, choice parameter, or entry index;

• the dereference of an access-to-constant value;

\{AI05-0015-1\} the return object declared by an extended return_statement with the reserved word constant;

\{AI05-0015-1\} the object denoted by result of evaluating a function_call or an aggregate;

\{AI05-0003-1\} the result of evaluating a qualified_expression;

\{AI05-0120-1\} within the body of a protected function (or a function declared immediately within a protected_body), the current instance of the enclosing protected unit;

• a selected_component, indexed_component, slice, or view conversion of a constant.

To be honest: \{AI95-00114-01\} A noninvertible view conversion to a general access type is also defined to be a constant—see 4.6.

\{AI05-0264-1\} At the place where a view of an object is defined, a nominal subtype is associated with the view. The object's actual subtype (that is, its subtype) can be more restrictive than the nominal subtype of the view; it always is if the nominal subtype is an indefinite subtype. A subtype is an indefinite subtype if it is an unconstrained array subtype, or if it has unknown discriminants or unconstrained discriminants...
without defaults (see 3.7); otherwise, the subtype is a definite subtype [(all elementary subtypes are definite subtypes)]. A class-wide subtype is defined to have unknown discriminants, and is therefore an indefinite subtype. An indefinite subtype does not by itself provide enough information to create an object; an additional constraint or explicit initialization expression is necessary (see 3.3.1). A component cannot have an indefinite nominal subtype.]

23.1/3 \{AI05-0008-1\} A view of a composite object is known to be constrained if:

- its nominal subtype is constrained, and is not an untagged partial view; or
- its nominal subtype is indefinite; or
- \{AI05-0008-1\} \{AI05-0093-1\} its type is immutably limited (see 7.5); or
- it is part of a stand-alone constant (including a generic formal object of mode in); or
- it is part of a formal parameter of mode in; or
- it is part of the object denoted by a function_call or aggregate; or
- it is part of a constant return object of an extended_return_statement; or
- \{AI05-0008-1\} \{AI05-0041-1\} it is a dereference of a pool-specific access type, and there is no ancestor of its type that has a constrained partial view.

Discussion: We do not include dereferences of general access types because they might denote stand-alone aliased unconstrained variables. That's true even for access-to-constant types (the denoted object does not have to be a constant).

23.10/3 \{AI05-0008-1\} \{AI05-0041-1\} For the purposes of determining within a generic body whether an object is known to be constrained:

- if a subtype is a descendant of an untagged generic formal private or derived type, and the subtype is not an unconstrained array subtype, it is not considered indefinite and is considered to have a constrained partial view;
- if a subtype is a descendant of a formal access type, it is not considered pool-specific.

A named number provides a name for a numeric value known at compile time. It is declared by a number_declaration.

NOTES

7 A constant cannot be the target of an assignment operation, nor be passed as an in out or out parameter, between its initialization and finalization, if any.

8 \{AI05-0054-2\} The value of a constant object cannot be changed after its initialization, except in some cases where the object has a controlled or immutably limited part (see 7.5, 7.6, and 13.9.1).

9 \{AI05-0264-1\} The nominal and actual subtypes of an elementary object are always the same. For a discriminated or array object, if the nominal subtype is constrained, then so is the actual subtype.

Extensions to Ada 83

There are additional kinds of objects (choice parameters and entry indices of entry bodies).

The result of a function and of evaluating an aggregate are considered (constant) objects. This is necessary to explain the action of finalization on such things. Because a function_call is also syntactically a name (see 4.1), the result of a function_call can be renamed, thereby allowing repeated use of the result without calling the function again.

Wording Changes from Ada 83

\{AI05-0299-1\} This subclause and its subclauses now follow the clause and subclauses on types and subtypes, to cut down on the number of forward references.
The term nominal subtype is new. It is used to distinguish what is known at compile time about an object's constraint, versus what its "true" run-time constraint is.

The terms definite and indefinite (which apply to subtypes) are new. They are used to aid in the description of generic formal type matching, and to specify when an explicit initial value is required in an object_declaration.

We have moved the syntax for object_declaration and number_declaration down into their respective subclauses, to keep the syntax close to the description of the associated semantics.

We talk about variables and constants here, since the discussion is not specific to object_declaration, and it seems better to have the list of the kinds of constants juxtaposed with the kinds of objects.

We no longer talk about indirect updating due to parameter passing. Parameter passing is handled in 6.2 and 6.4.1 in a way that there is no need to mention it here in the definition of read and update. Reading and updating now includes the case of evaluating or assigning to an enclosing object.

**Wording Changes from Ada 95**

\{AI95-00416-01\} Clarified that the return object is the object created by a function call.

**Extensions to Ada 2005**

\{AI05-0015-1\} Added wording to allow return objects to be declared as constants, and corrected the definition of return objects as objects.

**Wording Changes from Ada 2005**

\{AI05-0008-1\} \{AI05-0041-1\} \{AI05-0093-1\} **Correction:** Added a definition of known to be constrained, for use in other rules.

\{AI05-0054-2\} **Correction:** We now recognize the fact that not all declared constant objects are immutable; for those that a variable view can be constructed, they can be changed via that view.

\{AI05-0120-1\} **Correction:** Added the current instance of a protected object to the list of constant views; since the list claims to include all possibilities, it had better include that one.

\{AI05-0003-1\} The result of a qualified_expression is defined to be a constant view and is defined to be an object if the operand of the qualified_expression is an object. These definitions, combined with some grammar changes, allow qualified_expressions to be used in more places. See 4.1 for details.

### 3.3.1 Object Declarations

\{AI05-0262-1\} An object_declaration declares a stand-alone object with a given nominal subtype and, optionally, an explicit initial value given by an initialization expression. For an array, access_task, or protected object, the object_declaration may include the definition of the (anonymous) type of the object.

**Syntax**

\{AI95-00385-01\} \{AI95-00406-01\} \{AI05-0183-1\}

```
object_declaration ::= defining_identifier_list [aliased] [constant] subtype_indication [:= expression] [aspect_specification];
| defining_identifier_list [aliased] [constant] access_definition [:= expression] [aspect_specification];
| defining_identifier_list [aliased] [constant] array_type_definition [:= expression] [aspect_specification];
| single_task_declaration
| single_protected_declaration
| defining_identifier_list ::= defining_identifier {, defining_identifier}
```

**Name Resolution Rules**

For an object_declaration with an expression following the compound delimiter :=, the type expected for the expression is that of the object. This expression is called the initialization_expression.
Legality Rules

\{AI95-00287-01\} An object_declaration without the reserved word constant declares a variable object. If it has a subtype_indication or an array_type_definition that defines an indefinite subtype, then there shall be an initialization expression. An initialization expression shall not be given if the object is of a limited type.

Static Semantics

\{AI05-0264-1\} \{AI05-0299-1\} An object_declaration with the reserved word constant declares a constant object. If it has an initialization expression, then it is called a full constant declaration. Otherwise, it is called a deferred constant declaration. The rules for deferred constant declarations are given in subclause 7.4. The rules for full constant declarations are given in this subclause.

Any declaration that includes a defining_identifier_list with more than one defining_identifier is equivalent to a series of declarations each containing one defining_identifier from the list, with the rest of the text of the declaration copied for each declaration in the series, in the same order as the list. The remainder of this International Standard relies on this equivalence; explanations are given for declarations with a single defining_identifier.

\{AI95-00385-01\} The subtype_indication, access_definition, or full type definition of an object_declaration defines the nominal subtype of the object. The object_declaration declares an object of the type of the nominal subtype.

Discussion: \{AI95-00385-01\} The phrase “full type definition” here includes the case of an anonymous array, access, task, or protected type.

A component of an object is said to require late initialization if it has an access discriminant value constrained by a per-object expression, or if it has an initialization expression that includes a name denoting the current instance of the type or denoting an access discriminant.

Reason: Such components can depend on the values of other components of the object. We want to initialize them as late and as reproducibly as possible.

Dynamic Semantics

\{AI95-00363-01\} If a composite object declared by an object_declaration has an unconstrained nominal subtype, then if this subtype is indefinite or the object is constant or aliased (see 3.10) the actual subtype of this object is constrained. The constraint is determined by the bounds or discriminants (if any) of its initial value; the object is said to be constrained by its initial value. [In the case of an aliased object, this initial value may be either explicit or implicit; in the other cases, an explicit initial value is required.]

When not constrained by its initial value, the actual and nominal subtypes of the object are the same. If its actual subtype is constrained, the object is called a constrained object.

For an object_declaration without an initialization expression, any initial values for the object or its subcomponents are determined by the implicit initial values defined for its nominal subtype, as follows:

- The implicit initial value for an access subtype is the null value of the access type.

\{AI05-0228-1\} The implicit initial value for a scalar subtype that has the Default Value aspect specified is the value of that aspect converted to the nominal subtype (which might raise Constraint_Error — see 4.6, “Type Conversions”);

Ramification: This is a Dynamic Semantics rule, so the visibility of the aspect_specification is not relevant — if the full type for a private type has the Default Value aspect specified, partial views of the type also have this implicit initial value.

- The implicit initial (and only) value for each discriminant of a constrained discriminated subtype is defined by the subtype.
For a (definite) composite subtype, the implicit initial value of each component with a default_expression is obtained by evaluation of this expression and conversion to the component's nominal subtype (which might raise Constraint_Error — see 4.6, “Type Conversions”), unless the component is a discriminant of a constrained subtype (the previous case), or is in an excluded variant (see 3.8.1). For each component that does not have a default_expression, if the composite subtype has the Default Component Value aspect specified, the implicit initial value is the value of that aspect converted to the component's nominal subtype; otherwise, any implicit initial values are those determined by the component's nominal subtype.

For a protected or task subtype, there is an implicit component (an entry queue) corresponding to each entry, with its implicit initial value being an empty queue.

Implementation Note: The implementation may add implicit components for its own use, which might have implicit initial values. For a task subtype, such components might represent the state of the associated thread of control. For a type with dynamic-sized components, such implicit components might be used to hold the offset to some explicit component.

The elaboration of an object_declaration proceeds in the following sequence of steps:

1. The subtype_indication, access_definition, array_type_definition, single_task_declaration, or single_protected_declaration is first elaborated. This creates the nominal subtype (and the anonymous type in the last four latter three cases).

2. If the object_declaration includes an initialization expression, the (explicit) initial value is obtained by evaluating the expression and converting it to the nominal subtype (which might raise Constraint_Error — see 4.6).

3. The object is created, and, if there is not an initialization expression, the object is initialized by default. When an object is initialized by default, any per-object constraint expressions (see 3.8) are elaborated evaluated and any implicit initial values for the object or for its subcomponents are obtained as determined by the nominal subtype. Any initial values (whether explicit or implicit) are assigned to the object or to the corresponding subcomponents. As described in 5.2 and 7.6, Initialize and Adjust procedures can be called.

Discussion: For a per-object constraint that contains some per-object expressions and some non-per-object expressions, the values used for the constraint consist of the values of the non-per-object expressions evaluated at the point of the type_declaration, and the values of the per-object expressions evaluated at the point of the creation of the object.

The elaboration of per-object constraints was presumably performed as part of the dependent compatibility check in Ada 83. If the object is of a limited type with an access discriminant, the access_definition is elaborated at this time (see 3.7).

Reason: The reason we say that evaluating an explicit initialization expression happens before creating the object is that in some cases it is impossible to know the size of the object being created until its initial value is known, as in “X: String := Func_Call(...)”. The implementation can create the object early in the common case where the size can be known early, since this optimization is semantically neutral.

This paragraph was deleted.

Any initial values (whether explicit or implicit) are assigned to the object or to the corresponding subcomponents. As described in 5.2 and 7.6, Initialize and Adjust procedures can be called.

Ramification: Since the initial values have already been converted to the appropriate nominal subtype, the only Constraint Errors that might occur as part of these assignments are for values outside their base range that are used to initialize unconstrained numeric subcomponents. See 3.5.

For the third step above, the object creation and any elaborations and evaluations and assignments are performed in an arbitrary order subject to the following restrictions: except that if the default_expression for a discriminant is evaluated to obtain its initial value, then this evaluation is performed before that of the default_expression for any component that depends on the discriminant, and
also be before that of any default_expression that includes the name of the discriminant. The evaluations of
the third step and the assignments of the fourth step are performed in an arbitrary order, except that each
evaluation is performed before the resulting value is assigned.

- \{AI95-00373-01\} Assignment to any part of the object is preceded by the evaluation of the value
  that is to be assigned.
  
  **Reason:** Duh. But we ought to say it. Note that, like any rule in the International Standard, it doesn't prevent an "as-if"
optimization; as long as the semantics as observed from the program are correct, the compiler can generate any code it
wants.

- \{AI95-00373-01\} The evaluation of a default_expression that includes the name of a
discriminant is preceded by the assignment to that discriminant.
  
  **Reason:** Duh again. But we have to say this, too. It's odd that Ada 95 only required the default expressions to be
evaluated before the discriminant is used; it says nothing about discriminant values that come from
subtype_indications.

- \{AI95-00373-01\} The evaluation of the default_expression for any component that depends on a
discriminant is preceded by the assignment to that discriminant.
  
  **Reason:** For example:

```ada
type R(D : Integer := F) is
  record
    S : String(1..D) := (others => G);
  end record;
X : R;
```

For the elaboration of the declaration of X, it is important that F be evaluated before the aggregate.

- \{AI95-00373-01\} \{AI05-0092-1\} The assignments to any components, including implicit
components, not requiring late initialization must precede the initial value evaluations for any
components requiring late initialization; if two components both require late initialization, then
assignments to parts of the component occurring earlier in the order of the component
declarations must precede the initial value evaluations of the component occurring later.
  
  **Reason:** Components that require late initialization can refer to the entire object during their initialization. We want
them to be initialized as late as possible to reduce the chance that their initialization depends on uninitialized
components. For instance:

```ada
type T (D : Natural) is
  limited record
    C1 : T1 (T'Access);
    C2 : Natural := F (D);
    C3 : String (1 .. D) := (others => ' ');
  end record;
```

Component C1 requires late initialization. The initialization could depend on the values of any component of T,
including D, C2, or C3. Therefore, we want to it to be initialized last. Note that C2 and C3 do not require late
initialization; they only have to be initialized after D.

It is possible for there to be more than one component that requires late initialization. In this case, the language can't
prevent problems, because all of the components can't be the last one initialized. In this case, we specify the order of
initialization for components requiring late initialization; by doing so, programmers can arrange their code to avoid
accessing uninitialized components, and such arrangements are portable. Note that if the program accesses an
uninitialized component, 13.9.1 defines the execution to be erroneous.

- \{AI05-0228-1\} [There is no implicit initial value defined for a scalar subtype unless the Default Value
aspect has been specified for the type.] In the absence of an explicit initialization or the specification of
the Default Value aspect, a newly created scalar object might have a value that does not belong to its
subtype (see 13.9.1 and H.1).

  **To be honest:** It could even be represented by a bit pattern that doesn't actually represent any value of the type at all,
such as an invalid internal code for an enumeration type, or a NaN for a floating point type. It is a generally a bounded
error to reference scalar objects with such "invalid representations", as explained in 13.9.1, "Data Validity".

  **Ramification:** There is no requirement that two objects of the same scalar subtype have the same implicit initial
“value” (or representation). It might even be the case that two elaborations of the same object_declaration produce two
different initial values. However, any particular uninitialized object is default-initialized to a single value (or invalid
representation). Thus, multiple reads of such an uninitialized object will produce the same value each time (if the implementation chooses not to detect the error).

NOTES
10 Implicit initial values are not defined for an indefinite subtype, because if an object's nominal subtype is indefinite, an explicit initial value is required.
11 As indicated above, a stand-alone object is an object declared by an object_declaration. Similar definitions apply to “stand-alone constant” and “stand-alone variable.” A subcomponent of an object is not a stand-alone object, nor is an object that is created by an allocator. An object declared by a loop_parameter_specification, iterator_specification, parameter_specification, entry_index_specification, choice_parameter_specification, extended_return_statement, or a formal_object_declaration of mode in out is not considered a stand-alone object.
12 The type of a stand-alone object cannot be abstract (see 3.9.3).

Examples

Example of a multiple object declaration:

-- the multiple object declaration
{AI95-00433-01} John, Paul : not null Person_Name := new Person(Sex => M); -- see 3.10.1

-- is equivalent to the two single object declarations in the order given
{AI95-00433-01} John : not null Person_Name := new Person(Sex => M);
Paul : not null Person_Name := new Person(Sex => M);

Examples of variable declarations:

{AI95-00433-01} Count, Sum  : Integer;
Size        : Integer range 0 .. 10_000 := 0;
Sorted      : Boolean := False;
Color_Table :
array(1 .. Max) of Integer := (others => True);
Option      : Bit_Vector(1 .. 10) := (others => True);
Hello       : aliased constant String := "Hi, world.";
θ, φ        : Float range -π .. +π;

Examples of constant declarations:

{AI95-00433-01} Limit     : constant Integer := 10_000;
Low_Limit : constant Integer := Limit/10;
Tolerance : constant Real := Dispersion(1.15);
Hello_Msg : constant access String := Hello'Access; -- see 3.10.2

Extensions to Ada 83

The syntax rule for object_declaration is modified to allow the aliased reserved word.

A variable declared by an object_declaration can be constrained by its initial value; that is, a variable of a nominally unconstrained array subtype, or discriminated type without defaults, can be declared so long as it has an explicit initial value. In Ada 83, this was permitted for constants, and for variables created by allocators, but not for variables declared by object_declarations. This is particularly important for tagged class-wide types, since there is no way to constrain them explicitly, and so an initial value is the only way to provide a constraint. It is also important for generic formal private types with unknown discriminants.

We now allow an unconstrained_array_definition in an object_declaration. This allows an object of an anonymous array type to have its bounds determined by its initial value. This is for uniformity: If one can write “X: constant array(Integer range 1..10) of Integer := ...;” then it makes sense to also allow “X: constant array(Integer range <>) of Integer := ...;”. (Note that if anonymous array types are ever sensible, a common situation is for a table implemented as an array. Tables are often constant, and for constants, there's usually no point in forcing the user to count the number of elements in the value.)

Wording Changes from Ada 83

We have moved the syntax for object_declarations into this subclause.

Deferred constants no longer have a separate syntax rule, but rather are incorporated in object_declaration as constants declared without an initialization expression.
3.3.1 Object Declarations

3.3.2 Number Declarations

A number_declaration declares a named number.

Discussion: {AI05-0299-1} If a value or other property of a construct is required to be static that means it is required to be determined prior to execution. A static expression is an expression whose value is computed at compile time and is usable in contexts where the actual value might affect the legality of the construct. This is fully defined in subclause clause 4.9.

Syntax

number_declaration ::= defining_identifier_list : constant := static_expression;

Name Resolution Rules

3 The static_expression given for a number_declaration is expected to be of any numeric type.

Legality Rules

4/3 {AI05-0299-1} The static_expression given for a number declaration shall be a static expression, as defined by subclause clause 4.9.

Static Semantics

5 The named number denotes a value of type universal_integer if the type of the static_expression is an integer type. The named number denotes a value of type universal_real if the type of the static_expression is a real type.

6 The value denoted by the named number is the value of the static_expression, converted to the corresponding universal type.
Dynamic Semantics

The elaboration of a number_declaration has no effect.

Proof: Since the static_expression was evaluated at compile time.

Examples

Examples of number declarations:

Two_Pi        : constant := 2.0*Ada.Numerics.Pi;   -- a real number (see A.5)
{AI95-00433-01} Max           : constant := 500;                   -- an integer number
Max_Line_Size : constant := Max/6;                -- the integer 83
Power_16      : constant := 2**16;                 -- the integer 65_536
One, Un, Eins : constant := 1;                     -- three different names for 1

Extensions to Ada 83

We now allow a static expression of any numeric type to initialize a named number. For integer types, it was possible in Ada 83 to use 'Pos to define a named number, but there was no way to use a static expression of some nonuniversal real type to define a named number. This change is upward compatible because of the preference rule for the operators of the root numeric types.

Wording Changes from Ada 83

We have moved the syntax rule into this subclause.

We have moved the syntax rule into this subclause.

A183-00263 describes the elaboration of a number declaration in words similar to that of an object_declaration.

However, since there is no expression to be evaluated and no object to be created, it seems simpler to say that the elaboration has no effect.

3.4 Derived Types and Classes

A derived_type_definition defines a derived_type new_type (and its first subtype) whose characteristics are derived from those of a parent_type, and possibly from progenitor_types.

Glossary entry: A derived type is a type defined in terms of one or more other types given in a derived_type_definition. The first of those types is the parent type of the derived type and any others are progenitor types. Each class containing the parent type or a progenitor type also contains the derived type. The derived type inherits properties such as components and primitive operations from the parent and progenitors. A type together with the types derived from it (directly or indirectly) form a derivation class.

A class of types is a set of types that is closed under derivation; that is, if the parent or a progenitor type of a derived type belongs to a class, then so does the derived type. By saying that a particular group of types forms a class, we are saying that all derivatives of a type in the set inherit the characteristics that define that set. The more general term category of types is used for a set of types whose defining characteristics are not necessarily inherited by derivatives; for example, limited, abstract, and interface are all categories of types, but not classes of types.

Ramification: A class of types is also a category of types.

Syntax

\[
\text{derived_type_definition ::= } \begin{cases} 
\text{abstract} & \text{[limited] new parent_subtype_indication [and interface_list] record_extension_part} 
\end{cases}
\]

Legality Rules

The parent_subtype_indication defines the parent subtype; its type is the parent_type parent_type. The interface_list defines the progenitor types (see 3.9.4). A derived type has one parent type and zero or more progenitor types.
Glossary entry: The parent of a derived type is the first type given in the definition of the derived type. The parent can be almost any kind of type, including an interface type.

A type shall be completely defined (see 3.11.1) prior to being specified as the parent type in a derived_type_definition — [the full_type_declarations for the parent type and any of its subcomponents have to precede the derived_type_definition.]

Discussion: This restriction does not apply to the ancestor type of a private extension — see 7.3; such a type need not be completely defined prior to the private_extension_declaration. However, the restriction does apply to record extensions, so the ancestor type will have to be completely defined prior to the full_type_declaration corresponding to the private_extension_declaration.

Reason: We originally hoped we could relax this restriction. However, we found it too complex to specify the rules for a type derived from an incompletely defined limited type that subsequently became nonlimited.

{AI95-00401-01} If there is a record_extension_part, the derived type is called a record extension of the parent type. A record_extension_part shall be provided if and only if the parent type is a tagged type. [An interface_list shall be provided only if the parent type is a tagged type.]

Proof: {AI95-00401-01} The syntax only allows an interface_list to appear with a record_extension_part, and a record_extension_part can only be provided if the parent type is a tagged type. We give the last sentence anyway for completeness.

Implementation Note: We allow a record extension to inherit discriminants; an early version of Ada 9X did not. If the parent subtype is unconstrained, it can be implemented as though its discriminants were repeated in a new known_discriminant_part and then used to constrain the old ones one-for-one. However, in an extension aggregate, the discriminants in this case do not appear in the component association list.

Ramification: {AI95-00114-01} This rule needs to be rechecked in the visible part of an instance of a generic unit because of the "only if" part of the rule. For example:

5.a/2
generic
   type T is private;
   package P is
      type Der is new T;
   end P;

5.b/2
   package I is new P (Some_Tagged_Type); -- illegal

5.e/2
{AI95-00114-01} The instantiation is illegal because a tagged type is being extended in the visible part without a record_extension_part. Note that this is legal in the private part or body of an instance, both to avoid a contract model violation, and because no code that can see that the type is actually tagged can also see the derived type declaration.

5.f/2
No recheck is needed for derived types with a record_extension_part, as that has to be derived from something that is known to be tagged (otherwise the template is illegal).

5.1/3
{AI95-00419-01} {AI05-0096-1} If the reserved word limited appears in a derived_type_definition, the parent type shall be a limited type. If the parent type is a tagged formal type, then in addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Reason: We allow limited because we don't inherit limitedness from interfaces, so we must have a way to derive a limited type from interfaces. The word limited has to be legal when the parent could be an interface, and that includes generic formal abstract types. Since we have to allow it in this case, we might as well allow it everywhere as documentation, to make it explicit that the type is limited.

However, we do not want to allow limited when the parent is nonlimited: limitedness cannot change in a derivation tree.

5.i/3
If the parent type is an untagged limited formal type with an actual type that is nonlimited, we allow derivation as a limited type in the private part or body as no place could have visibility on the resulting type where it was known to be nonlimited (outside of the instance). (See the previous paragraph's annotations for an explanation of this.) However, if the parent type is a tagged limited formal type with an actual type that is nonlimited, it would be possible to pass a value of the limited type extension to a class-wide type of the parent, which would be nonlimited. That's too weird to allow (even though all of the extension components would have to be nonlimited because the rules of 3.9.1 are rechecked), so we have a special rule to prevent that in the private part (type extension from a formal type is illegal in a generic package body).
Static Semantics

The first subtype of the derived type is unconstrained if a known_discriminant_part is provided in the declaration of the derived type, or if the parent subtype is unconstrained. Otherwise, the constraint of the first subtype corresponds to that of the parent subtype in the following sense: it is the same as that of the parent subtype except that for a range constraint (implicit or explicit), the value of each bound of its range is replaced by the corresponding value of the derived type.

Discussion: A digits_constraint in a subtype_indication for a decimal fixed point subtype always imposes a range constraint, implicitly if there is no explicit one given. See 3.5.9, “Fixed Point Types”.

\{AI95-00231-01\} The first subtype of the derived type excludes null (see 3.10) if and only if the parent subtype excludes null.

\{AI05-0110-1\} The characteristics and implicitly declared primitive subprograms characteristics of the derived type are defined as follows:

Ramification: \{AI05-0110-1\} The characteristics of a type do not include its primitive subprograms (primitive subprograms include predefined operators). The rules governing availability/visibility and inheritance of characteristics are separate from those for primitive subprograms.

- \{AI95-00251-01\} \{AI95-00401-01\} \{AI95-00442-01\} [If the parent type or a progenitor type belongs to a class of types, then the derived type also belongs to that class.] The following sets of types, as well as any higher-level sets composed from them, are classes in this sense[, and hence the characteristics defining these classes are inherited by derived types from their parent or progenitor types]: signed integer, modular integer, ordinary fixed, decimal fixed, floating point, enumeration, boolean, character, access-to-constant, general access-to-variable, pool-specific access-to-variable, access-to-subprogram, array, string, non-array composite, nonlimited, untagged record, tagged, task, protected, and synchronized tagged

Each class of types that includes the parent type also includes the derived type.

Discussion: This is inherent in our notion of a “class” of types. It is not mentioned in the initial definition of “class” since at that point type derivation has not been defined. In any case, this rule ensures that every class of types is closed under derivation.

- If the parent type is an elementary type or an array type, then the set of possible values of the derived type is a copy of the set of possible values of the parent type. For a scalar type, the base range of the derived type is the same as that of the parent type.

Discussion: The base range of a type defined by an integer_type_definition or a real_type_definition is determined by the _definition, and is not necessarily the same as that of the corresponding root numeric type from which the newly defined type is implicitly derived. Treating numerics types as implicitly derived from one of the two root numeric types is simply to link them into a type hierarchy; such an implicit derivation does not follow all the rules given here for an explicit derived_type_definition.

- If the parent type is a composite type other than an array type, then the components, protected subprograms, and entries that are declared for the derived type are as follows:

  - The discriminants specified by a new known_discriminant_part, if there is one; otherwise, each discriminant of the parent type (implicitly declared in the same order with the same specifications) — in the latter case, the discriminants are said to be inherited, or if unknown in the parent, are also unknown in the derived type;

  - Each nondiscriminant component, entry, and protected subprogram of the parent type, implicitly declared in the same order with the same declarations; these components, entries, and protected subprograms are said to be inherited;

Ramification: The profiles of entries and protected subprograms do not change upon type derivation, although the type of the “implicit” parameter identified by the prefix of the name in a call does.

To be honest: Any name in the parent type_declaration that denotes the current instance of the type is replaced with a name denoting the current instance of the derived type, converted to the parent type.

- Each component declared in a record_extension_part, if any.
Declarations of components, protected subprograms, and entries, whether implicit or explicit, occur immediately within the declarative region of the type, in the order indicated above, following the parent subtype_indication.

Discussion: The order of declarations within the region matters for record_aggregates and extension_aggregates.

Ramification: In most cases, these things are implicitly declared immediately following the parent subtype_indication. However, 7.3.1, “Private Operations” defines some cases in which they are implicitly declared later, and some cases in which they are not declared at all.

Discussion: The place of the implicit declarations of inherited components matters for visibility — they are not visible in the known_discriminant_part nor in the parent subtype_indication, but are usually visible within the record_extension_part, if any (although there are restrictions on their use). Note that a discriminant specified in a new known_discriminant_part is not considered “inherited” even if it has the same name and subtype as a discriminant of the parent type.

This paragraph was deleted. [AI95-00419-01] The derived type is limited if and only if the parent type is limited.

To be honest: [AI95-00419-01] The derived type can become nonlimited if the derivation takes place in the visible part of a child package, and the parent type is nonlimited as viewed from the private part of the child package — see 7.4.

[For each predefined operator of the parent type, there is a corresponding predefined operator of the derived type.]

Proof: This is a ramification of the fact that each class that includes the parent type also includes the derived type, and the fact that the set of predefined operators that is defined for a type, as described in 4.5, is determined by the classes to which it belongs.

Reason: Predefined operators are handled separately because they follow a slightly different rule than user-defined primitive subprograms. In particular the systematic replacement described below does not apply fully to the relational operators for Boolean and the exponentiation operator for Integer. The relational operators for a type derived from Boolean still return Standard.Boolean. The exponentiation operator for a type derived from Integer still expects Standard.Integer for the right operand. In addition, predefined operators "reemerge" when a type is the actual type corresponding to a generic formal type, so they need to be well defined even if hidden by user-defined primitive subprograms.

{AI95-00401-01} For each user-defined primitive subprogram (other than a user-defined equality operator — see below) of the parent type or of a progenitor type that already exists at the place of the derived_type_definition, there exists a corresponding inherited primitive subprogram of the derived type with the same defining name. Primitive user-defined equality operators of the parent type and any progenitor types are also inherited by the derived type, except when the derived type is a nonlimited record extension, and the inherited operator would have a profile that is type conformant with the profile of the corresponding predefined equality operator; in this case, the user-defined equality operator is not inherited, but is rather incorporated into the implementation of the predefined equality operator of the record extension (see 4.5.2).

Ramification: We say “...already exists...” rather than “is visible” or “has been declared” because there are certain operations that are declared later, but still exist at the place of the derived_type_definition, and there are operations that are never declared, but still exist. These cases are explained in 7.3.1.

Note that nonprivate extensions can appear only after the last primitive subprogram of the parent — the freezing rules ensure this.

Reason: A special case is made for the equality operators on nonlimited record extensions because their predefined equality operators are already defined in terms of the primitive equality operator of their parent type (and of the tagged components of the extension part). Inheriting the parent's equality operator as is would be undesirable, because it would ignore any components of the extension part. On the other hand, if the parent type is limited, then any user-defined equality operator is inherited as is, since there is no predefined equality operator to take its place.

Ramification: [AI95-00114-01] Because user-defined equality operators are not inherited by nonlimited_record extensions, the formal parameter names of = and /= revert to Left and Right, even if different formal parameter names were used in the user-defined equality operators of the parent type.

Discussion: [AI95-00401-01] This rule only describes what operations are inherited; the rules that describe what happens when there are conflicting inherited subprograms are found in 8.3.
The profile of an inherited subprogram (including an inherited enumeration literal) is obtained from the profile of the corresponding (user-defined) primitive subprogram of the parent or progenitor type, after systematic replacement of each subtype of its profile (see 6.1) that is of the parent or progenitor type, other than those subtypes found in the designated profile of an access_definition, with a corresponding subtype of the derived type. For a given subtype of the parent or progenitor type, the corresponding subtype of the derived type is defined as follows:

- If the declaration of the derived type has neither a known_discriminant_part nor a record_extension_part, then the corresponding subtype has a constraint that corresponds (as defined above for the first subtype of the derived type) to that of the given subtype.
- If the derived type is a record extension, then the corresponding subtype is the first subtype of the derived type.
- If the derived type has a new known_discriminant_part but is not a record extension, then the corresponding subtype is constrained to those values that when converted to the parent type belong to the given subtype (see 4.6).

**Reason:** An inherited subprogram of an untagged type has an Intrinsic calling convention, which precludes the use of the Access attribute. We preclude Access because correctly performing all required constraint checks on an indirect call to such an inherited subprogram was felt to impose an undesirable implementation burden.

**Note:** The exception to substitution of the parent or progenitor type applies only in the profiles of anonymous access-to-subprogram types. The exception is necessary to avoid calling an access-to-subprogram with types and/or constraints different than expected by the actual routine.

All numeric types are derived types, in that they are implicitly derived from a corresponding root numeric type (see 3.5.4 and 3.5.6).

**Dynamic Semantics**

The elaboration of a derived_type_definition creates the derived type and its first subtype, and consists of the elaboration of the subtype_indication and the record_extension_part, if any. If the subtype_indication depends on a discriminant, then only those expressions that do not depend on a discriminant are evaluated.

**Discussion:** We don't mention the interface_list, because it does not need elaboration (see 3.9.4). This is consistent with the handling of discriminant parts, which aren't elaborated either.

For the execution of a call on an inherited subprogram, a call on the corresponding primitive subprogram of the parent or progenitor type is performed; the normal conversion of each actual parameter to the subtype of the corresponding formal parameter (see 6.4.1) performs any necessary type conversion as well. If the result type of the inherited subprogram is the derived type, the...
result of calling the parent's subprogram of the parent or progenitor is converted to the derived type, or in the case of a null extension, extended to the derived type using the equivalent of an extension aggregate with the original result as the ancestor part and null record as the record component association list.

Discussion: {AI95-00391-01} If an inherited function returns the derived type, and the type is a nonnull record extension, then the inherited function shall be overridden, unless the type is abstract (in which case the function is abstract, and (unless overridden) cannot be called except via a dispatching call). See 3.9.3.

NOTES
13 Classes are closed under derivation — any class that contains a type also contains its derivatives. Operations available for a given class of types are available for the derived types in that class.
14 Evaluating an inherited enumeration literal is equivalent to evaluating the corresponding enumeration literal of the parent type, and then converting the result to the derived type. This follows from their equivalence to parameterless functions.
15 A generic subprogram is not a subprogram, and hence cannot be a primitive subprogram and cannot be inherited by a derived type. On the other hand, an instance of a generic subprogram can be a primitive subprogram, and hence can be inherited.
16 If the parent type is an access type, then the parent and the derived type share the same storage pool; there is a null access value for the derived type and it is the implicit initial value for the type. See 3.10.
17 If the parent type is a boolean type, the predefined relational operators of the derived type deliver a result of the predefined type Boolean (see 4.5.2). If the parent type is an integer type, the right operand of the predefined exponentiation operator is of the predefined type Integer (see 4.5.6).
18 Any discriminants of the parent type are either all inherited, or completely replaced with a new set of discriminants.
19 For an inherited subprogram, the subtype of a formal parameter of the derived type need not have any value in common with the first subtype of the derived type.

Proof: This happens when the parent subtype is constrained to a range that does not overlap with the range of a subtype of the parent type that appears in the profile of some primitive subprogram of the parent type. For example:

```ada
type T1 is range 1..100;
subtype S1 is T1 range 1..10;
procedure P(X : in S1);    -- P is a primitive subprogram
type T2 is new T1 range 11..20;
  -- implicitly declared:
  -- procedure P(X : in T2'Base range 1..10);
  -- X cannot be in T2'First .. T2'Last;
```

20 If the reserved word abstract is given in the declaration of a type, the type is abstract (see 3.9.3).

Examples of derived type declarations:

```ada
type Local_Coordinate is new Coordinate;    -- two different types
type Midweek is new Day range Tue .. Thu;   -- see 3.5.1
type Counter is new Positive;               -- same range as Positive

type Special_Key is new Key_Manager.Key;   -- see 7.3.1
  -- the inherited subprograms have the following specifications:
  -- procedure Get_Key(K : out Special_Key);
  -- function "<"(X,Y : Special_Key) return Boolean;
```

Examples of derived type declarations:

```ada

3.4 Derived Types and Classes 13 December 2012 68
```
Incompatibilities With Ada 83

When deriving from a (nonprivate, nonderived) type in the same visible part in which it is defined, a primitive subprogram of the parent type declared before the derived type will be inherited by the derived type. This can cause upward incompatibilities in cases like this:

```ada
package P is
   type T is (A, B, C, D);
   function F( X : T := A ) return Integer;
   type NT is new T;
   -- inherits F as
   -- function F( X : NT := A ) return Integer;
   -- in Ada 95 only
   ...
end P;
...
use P; -- Only one declaration of F from P is use-visible in
-- Ada 83: two declarations of F are use-visible in
-- Ada 95.
begin
   ...
   if F > 1 then ... -- legal in Ada 83, ambiguous in Ada 95
```

Extensions to Ada 83

The syntax for a derived_type_definition is amended to include an optional record_extension_part (see 3.9.1).

A derived type may override the discriminants of the parent by giving a new discriminant_part.

The parent type in a derived_type_definition may be a derived type defined in the same visible part.

When deriving from a type in the same visible part in which it is defined, the primitive subprograms declared prior to the derivation are inherited as primitive subprograms of the derived type: See 3.2.3.

Wording Changes from Ada 83

We now talk about the classes to which a type belongs, rather than a single class.

{AI05-0190-01} As explained in Section 13, the concept of "storage pool" replaces the Ada 83 concept of "collection." These concepts are similar, but not the same.

Extensions to Ada 95

{AI95-00251-01} {AI95-00401-01} A derived type may inherit from multiple (interface) progenitors, as well as the parent type — see 3.9.4, “Interface Types”.

{AI95-00419-01} A derived type may specify that it is a limited type. This is required for interface ancestors (from which limitedness is not inherited), but it is generally useful as documentation of limitedness.

Wording Changes from Ada 95

{AI95-00391-01} Defined the result of functions for null extensions (which we no longer require to be overridden - see 3.9.3).

{AI95-00442-01} Defined the term “category of types” and used it in wording elsewhere; also specified the language-defined categories that form classes of types (this was never normatively specified in Ada 95).

Incompatibilities With Ada 2005

{AI05-0096-1} **Correction:** Added a (re)check that limited type extensions never are derived from nonlimited types in generic private parts. This is disallowed as it would make it possible to pass a limited object to a nonlimited class-wide type, which could then be copied. This is only possible using Ada 2005 syntax, so examples in existing programs should be rare.

Wording Changes from Ada 2005

{AI05-0110-1} **Correction:** Added wording to clarify that the characteristics of derived types are formally defined here. (This is the only place in the Standard that actually spells out what sorts of things are actually characteristics, which is rather important.)

{AI05-0164-1} **Correction:** Added wording to ensure that anonymous access-to-subprogram types don't get modified on derivation.
3.4.1 Derivation Classes

In addition to the various language-defined classes of types, types can be grouped into derivation classes.

**Static Semantics**

\{AI95-00251-01\} \{AI95-00401-01\} A derived type is derived from its parent type directly; it is derived indirectly from any type from which its parent type is derived. A derived type, interface type, type extension, task type, protected type, or formal derived type is also derived from every ancestor of each of its progenitor types, if any. The derivation class of types for a type T (also called the class rooted at T) is the set consisting of T (the root type of the class) and all types derived from T (directly or indirectly) plus any associated universal or class-wide types (defined below).

**Discussion:** Note that the definition of “derived from” is a recursive definition. We don’t define a root type for all interesting language-defined classes, though presumably we could.

To be honest: By the class-wide type “associated” with a type T, we mean the type T’Class. Similarly, the universal type associated with root_integer, root_real, and root_fixed are universal_integer, universal_real, and universal_fixed, respectively.

\{AI95-00230-01\} Every type is either a specific type, a class-wide type, or a universal type. A specific type is one defined by a type_declaration, a formal_type_declaration, or a full type definition embedded in another construct declaration for an object. Class-wide and universal types are implicitly defined, to act as representatives for an entire class of types, as follows:

**To be honest:** The root types root_integer, root_real, and root_fixed are also specific types. They are declared in the specification of package Standard.

**Class-wide types**

Class-wide types are defined for [(and belong to)] each derivation class rooted at a tagged type (see 3.9). Given a subtype S of a tagged type T, S’Class is the subtype_mark for a corresponding subtype of the tagged class-wide type T’Class. Such types are called “class-wide” because when a formal parameter is defined to be of a class-wide type T’Class, an actual parameter of any type in the derivation class rooted at T is acceptable (see 8.6).

The set of values for a class-wide type T’Class is the discriminated union of the set of values of each specific type in the derivation class rooted at T (the tag acts as the implicit discriminant — see 3.9). Class-wide types have no primitive subprograms of their own. However, as explained in 3.9.2, operands of a class-wide type T’Class can be used as part of a dispatching call on a primitive subprogram of the type T. The only components [(including discriminants)] of T’Class that are visible are those of T. If S is a first subtype, then S’Class is a first subtype.

**Reason:** We want S’Class to be a first subtype when S is, so that an attribute_definition_clause like “for S’Class'Output use ...;” will be legal.

**Universal types**

Universal types are defined for [(and belong to)] the integer, real, and fixed point, and access classes, and are referred to in this standard as respectively, universal_integer, universal_real, and universal_fixed and universal_access. These are analogous to class-wide types for these language-defined elementary numeric classes. As with class-wide types, if a formal parameter is of a universal type, then an actual parameter of any type in the corresponding class is acceptable. In addition, a value of a universal type (including an integer or real numeric_literal, or the literal null) is “universal” in that it is acceptable where some particular type in the class is expected (see 8.6).

The set of values of a universal type is the undiscriminated union of the set of values possible for any definable type in the associated class. Like class-wide types, universal types have no
primitive subprograms of their own. However, their “universality” allows them to be used as
operands with the primitive subprograms of any type in the corresponding class.

Discussion: A class-wide type is only class-wide in one direction, from specific to class-wide, whereas a universal
type is class-wide (universal) in both directions, from specific to universal and back.

\{AI95-00230-01\} We considered defining class-wide or perhaps universal types for all derivation classes, not just
tagged classes and these four elementary three numeric classes. However, this was felt to overly weaken the strong-
typing model in some situations. Tagged types preserve strong type distinctions thanks to the run-time tag. Class-wide
or universal types for untagged types would weaken the compile-time type distinctions without providing a
compensating run-time-checkable distinction.

We considered defining standard names for the universal numeric types so they could be used in formal parameter
 specifications. However, this was felt to impose an undue implementation burden for some implementations.

To be honest: Formally, the set of values of a universal type is actually a copy of the undiscriminated union of the
values of the types in its class. This is because we want each value to have exactly one type, with explicit or implicit
conversion needed to go between types. An alternative, consistent model would be to associate a class, rather than a
particular type, with a value, even though any given expression would have a particular type. In that case, implicit type
conversions would not generally need to change the value, although an associated subtype conversion might need to.

The integer and real numeric classes each have a specific root type in addition to their universal type,
named respectively root_integer and root_real.

A class-wide or universal type is said to cover all of the types in its class. A specific type covers only
itself.

\{AI95-00230-01\} \{AI95-00251-01\} A specific type \(T2\) is defined to be a descendant of a type \(T1\) if \(T2\) is
the same as \(T1\), or if \(T2\) is derived (directly or indirectly) from \(T1\). A class-wide type \(T2\) Class is defined
to be a descendant of type \(T1\) if \(T2\) is a descendant of \(T1\). Similarly, the numeric universal types are
defined to be descendants of the root types of their classes. If a type \(T2\) is a descendant of a type \(T1\), then
\(T1\) is called an ancestor of \(T2\). AnThe ultimate ancestor of a type is the ancestor of that the type that is not
itself a descendant of any other type. Every untagged type has a unique ultimate ancestor.

Ramification: A specific type is a descendant of itself. Class-wide types are considered descendants of the
corresponding specific type, and do not have any descendants of their own.

A specific type is an ancestor of itself. The root of a derivation class is an ancestor of all types in the class, including
any class-wide types in the class.

Discussion: The terms root, parent, ancestor, and ultimate ancestor are all related. For example:

- \{AI95-00251-01\} Each type has at most one parent, and one or more ancestor types; each untagged type has
  exactly one ultimate ancestor. In Ada 83, the term “parent type” was sometimes used more generally to
  include any ancestor type (e.g. RM83-9.4(14)). In Ada 95, we restrict parent to mean the immediate ancestor.
- A class of types has at most one root type; a derivation class has exactly one root type.
- The root of a class is an ancestor of all of the types in the class (including itself).
- The type root_integer is the root of the integer class, and is the ultimate ancestor of all integer types. A
  similar statement applies to root_real.

Glossary entry: An ancestor of a type is the type itself or, in the case of a type derived from other types, its parent
type or one of its progenitor types or one of their ancestors. Note that ancestor and descendant are inverse
relationships.

Glossary entry: A type is a descendant of itself, its parent and progenitor types, and their ancestors. Note that
descendant and ancestor are inverse relationships.

An inherited component [(including an inherited discriminant)] of a derived type is inherited from a given
ancestor of the type if the corresponding component was inherited by each derived type in the chain of
derivations going back to the given ancestor.

NOTES

23 Because operands of a universal type are acceptable to the predefined operators of any type in their class, ambiguity can
result. For universal_integer and universal_real, this potential ambiguity is resolved by giving a preference (see 8.6) to the
predefined operators of the corresponding root types (root_integer and root_real, respectively). Hence, in an apparently
ambiguous expression like
where each of the literals is of type \textit{universal	extunderscore integer}, the predefined operators of \textit{root	extunderscore integer} will be preferred over those of other specific integer types, thereby resolving the ambiguity.

\textbf{Ramification:} Except for this preference, a root numeric type is essentially like any other specific type in the associated numeric class. In particular, the result of a predefined operator of a root numeric type is not “universal” (implicitly convertible) even if both operands were.

\textit{Wording Changes from Ada 95}

{\{AI95-00230-01\}} Updated the wording to define the \textit{universal access type}. This was defined to make \texttt{null} for anonymous access types sensible.

{\{AI95-00251-01\}} The definitions of ancestors and descendants were updated to allow multiple ancestors (necessary to support interfaces).

\section*{3.5 Scalar Types}

\textit{Scalar} types comprise enumeration types, integer types, and real types. Enumeration types and integer types are called \textit{discrete} types; each value of a discrete type has a \textit{position number} which is an integer value. Integer types and real types are called \textit{numeric} types. [All scalar types are ordered, that is, all relational operators are predefined for their values.]

\textit{Syntax}

\begin{verbatim}
range_constraint ::= range range
range ::= range_attribute_reference
        | simple_expression .. simple_expression
\end{verbatim}

\textbf{Discussion:} These need to be \texttt{simple	extunderscore expression}s rather than more general \texttt{expression}s because ranges appear in membership tests and other contexts where \texttt{expression} \texttt{.. expression} would be ambiguous.

A \textit{range} has a \texttt{lower bound} and an \texttt{upper bound} and specifies a subset of the values of some scalar type (the \texttt{type of the range}). A range with lower bound \texttt{L} and upper bound \texttt{R} is described by \texttt{“L .. R”}. If \texttt{R} is less than \texttt{L}, then the range is a \textit{null range}, and specifies an empty set of values. Otherwise, the range specifies the values of the type from the lower bound to the upper bound, inclusive. A value \textit{belongs} to a range if it is of the type of the range, and is in the subset of values specified by the range. A value \textit{satisfies} a range constraint if it belongs to the associated range. One range is \textit{included} in another if all values that belong to the first range also belong to the second.

\textit{Name Resolution Rules}

For a \texttt{subtype	extunderscore indication} containing a \texttt{range	extunderscore constraint}, either directly or as part of some other \texttt{scalar	extunderscore constraint}, the type of the \texttt{range} shall resolve to that of the type determined by the \texttt{subtype	extunderscore mark} of the \texttt{subtype	extunderscore indication}. For a range of a given type, the \texttt{simple	extunderscore expression}s of the \texttt{range} (likewise, the \texttt{simple	extunderscore expression}s of the equivalent \texttt{range} for a \texttt{range	extunderscore attribute	extunderscore reference}) are expected to be of the \texttt{type of the range}.

\textbf{Discussion:} In Ada 95, constraints only appear within \texttt{subtype	extunderscore indications}; things that look like constraints that appear in type declarations are called something else like \texttt{real	extunderscore range	extunderscore specifications}.

{\{AI05-0299-1\}} We say “the expected type is ...” or “the type is expected to be ...” depending on which reads better. They are fundamentally equivalent, and both feed into the type resolution rules of subclause \texttt{8.6}.

In some cases, it doesn't work to use expected types. For example, in the above rule, we say that the “type of the range shall resolve to ...” rather than “the expected type for the range is ...”. We then use “expected type” for the bounds. If we used “expected” at both points, there would be an ambiguity, since one could apply the rules of 8.6 either on determining the type of the range, or on determining the types of the individual bounds. It is clearly important to allow one bound to be of a universal type, and the other of a specific type, so we need to use “expected type” for the bounds. Hence, we used “shall resolve to” for the type of the range as a whole. There are other situations where “expected type” is not quite right, and we use “shall resolve to” instead.
Static Semantics

The base range of a scalar type is the range of finite values of the type that can be represented in every unconstrained object of the type; it is also the range supported at a minimum for intermediate values during the evaluation of expressions involving predefined operators of the type.

**Implementation Note:** Note that in some machine architectures intermediates in an expression (particularly if static), and register-resident variables might accommodate a wider range. The base range does not include the values of this wider range that are not assignable without overflow to memory-resident objects.

**Ramification:** The base range of an enumeration type is the range of values of the enumeration type.

**Reason:** If the representation supports infinities, the base range is nevertheless restricted to include only the representable finite values, so that 'Base'First and 'Base'Last are always guaranteed to be finite.

**To be honest:** By a "value that can be assigned without overflow" we don't mean to restrict ourselves to values that can be represented exactly. Values between machine representable values can be assigned, but on subsequent reading, a slightly different value might be retrieved, as (partially) determined by the number of digits of precision of the type.

[A constrained scalar subtype is one to which a range constraint applies.] The range of a constrained scalar subtype is the range associated with the range constraint of the subtype. The range of an unconstrained scalar subtype is the base range of its type.

Dynamic Semantics

A range is compatible with a scalar subtype if and only if it is either a null range or each bound of the range belongs to the range of the subtype. A range_constraint is compatible with a scalar subtype if and only if its range is compatible with the subtype.

**Ramification:** Only range_constraints (explicit or implicit) impose conditions on the values of a scalar subtype. The other scalar_constraints, digits_constraints and delta_constraints impose conditions on the subtype denoted by the subtype_mark in a subtype_indication, but don't impose a condition on the values of the subtype being defined. Therefore, a scalar subtype is not called constrained if all that applies to it is a digits_constraint. Decimal subtypes are subtle, because a digits_constraint without a range_constraint nevertheless includes an implicit range_constraint.

The elaboration of a range_constraint consists of the evaluation of the range. The evaluation of a range determines a lower bound and an upper bound. If simple_expressions are given to specify bounds, the evaluation of the range evaluates these simple_expressions in an arbitrary order, and converts them to the type of the range. If a range_attribute_reference is given, the evaluation of the range consists of the evaluation of the range_attribute_reference.

**Attributes**

For every scalar subtype S, the following attributes are defined:

S'First  
S'First denotes the lower bound of the range of S. The value of this attribute is of the type of S.

**Ramification:** Evaluating S'First never raises Constraint_Error.

S'Last  
S'Last denotes the upper bound of the range of S. The value of this attribute is of the type of S.

**Ramification:** Evaluating S'Last never raises Constraint_Error.

S'Range  
S'Range is equivalent to the range S'First .. S'Last.

S'Base  
S'Base denotes an unconstrained subtype of the type of S. This unconstrained subtype is called the base subtype of the type.

S'Min  
S'Min denotes a function with the following specification:

```ada
function S'Min(Left, Right : S'Base) return S'Base
```

The function returns the lesser of the values of the two parameters.

3.5  Scalar Types  

18.a  Discussion: The formal parameter names are italicized because they cannot be used in calls — see 6.4. Such a specification cannot be written by the user because an attribute_reference is not permitted as the designator of a user-defined function, nor can its formal parameters be anonymous.

19  S'Max  

S'Max denotes a function with the following specification:

```ada
function S'Max(Left, Right : S'Base)
return S'Base
```

The function returns the greater of the values of the two parameters.

22  S'Succ  

S'Succ denotes a function with the following specification:

```ada
function S'Succ(Arg : S'Base)
return S'Base
```

For an enumeration type, the function returns the value whose position number is one more than that of the value of Arg; Constraint_Error is raised if there is no such value of the type. For an integer type, the function returns the result of adding one to the value of Arg. For a fixed point type, the function returns the result of adding small to the value of Arg. For a floating point type, the function returns the machine number (as defined in 3.5.7) immediately above the value of Arg; Constraint_Error is raised if there is no such machine number.

24.a  Ramification: S'Succ for a modular integer subtype wraps around if the value of Arg is S'Base'Last. S'Succ for a signed integer subtype might raise Constraint_Error if the value of Arg is S'Base'Last, or it might return the out-of-base-range value S'Base'Last+1, as is permitted for all predefined numeric operations.

25  S'Pred  

S'Pred denotes a function with the following specification:

```ada
function S'Pred(Arg : S'Base)
return S'Base
```

For an enumeration type, the function returns the value whose position number is one less than that of the value of Arg; Constraint_Error is raised if there is no such value of the type. For an integer type, the function returns the result of subtracting one from the value of Arg. For a fixed point type, the function returns the result of subtracting small from the value of Arg. For a floating point type, the function returns the machine number (as defined in 3.5.7) immediately below the value of Arg; Constraint_Error is raised if there is no such machine number.

27.a  Ramification: S'Pred for a modular integer subtype wraps around if the value of Arg is S'Base'First. S'Pred for a signed integer subtype might raise Constraint_Error if the value of Arg is S'Base'First, or it might return the out-of-base-range value S'Base'First–1, as is permitted for all predefined numeric operations.

27.1/2  S'Wide_Wide_Image  

{AI95-00285-01} S'Wide_Wide_Image denotes a function with the following specification:

```ada
function S'Wide_Wide_Image(Arg : S'Base)
return Wide_Wide_String
```

The function returns an image of the value of Arg, that is, a sequence of characters representing the value in display form. The lower bound of the result is one.

The image of an integer value is the corresponding decimal literal, without underlines, leading zeros, exponent, or trailing spaces, but with a single leading character that is either a minus sign or a space.

Implementation Note: If the machine supports negative zeros for signed integer types, it is not specified whether "0" or "-0" should be returned for negative zero. We don't have enough experience with such machines to know what is appropriate, and what other languages do. In any case, the implementation should be consistent.

The image of an enumeration value is either the corresponding identifier in upper case or the corresponding character literal (including the two apostrophes); neither leading nor trailing spaces are included. For a nongraphic character (a value of a character type that has no enumeration literal associated with it), the result is a corresponding language-defined name in
upper case (for example, the image of the nongraphic character identified as \texttt{nul} is “NUL”—the quotes are not part of the image).

**Implementation Note:** For an enumeration type \( T \) that has “holes” (caused by an \texttt{enumeration_representation-clause}), \( T'\text{Wide\_Image} \) should raise \texttt{Program\_Error} if the value is one of the holes (which is a bounded error anyway, since holes can be generated only via uninitialized variables and similar things).

The image of a floating point value is a decimal real literal best approximating the value (rounded away from zero if halfway between) with a single leading character that is either a minus sign or a space, a single digit (that is nonzero unless the value is zero), a decimal point, \( S'Digits - 1 \) (see 3.5.8) digits after the decimal point (but one if \( S'Digits \) is one), an upper case \( E \), the sign of the exponent (either + or –), and two or more digits (with leading zeros if necessary) representing the exponent. If \( S'Signed\_Zeros \) is True, then the leading character is a minus sign for a negatively signed zero.

**Reason:** This image is intended to conform to that produced by \texttt{Text\_IO.Float\_IO.Put} in its default format.

**Implementation Note:** The rounding direction is specified here to ensure portability of output results.

To be honest: Leading zeros are present in the exponent only if necessary to make the exponent at least two digits.

**Reason:** This image is intended to conform to that produced by \texttt{Text\_IO.Fixed\_IO.Put}.

**Implementation Note:** The rounding direction is specified here to ensure portability of output results.

**Implementation Note:** For a machine that supports negative zeros, it is not specified whether "\texttt{0.000}" or "\texttt{–0.000}" is returned. See corresponding comment above about integer types with signed zeros.

\texttt{S'Wide\_Image}

\texttt{S'Wide\_Image} denotes a function with the following specification:

\begin{verbatim}
function S'Wide\_Image(Arg : S'Base) return Wide\_String
{AI95-00285-01} {AI05-0262-1} {AI05-0264-1} The function returns an image of the value of \( Arg \) as a \texttt{Wide\_String}, that is, a sequence of characters representing the value in display form. The lower bound of the result is one. The image has the same sequence of graphic characters as defined for \texttt{S'Wide\_Wide\_Image} if all the graphic characters are defined in \texttt{Wide\_Character}; otherwise, the sequence of characters is implementation defined (but no shorter than that of \texttt{S'Wide\_Wide\_Image} for the same value of \( Arg \)).

**Implementation defined:** The sequence of characters of the value returned by \texttt{S'Wide\_Image} when some of the graphic characters of \texttt{S'Wide\_Wide\_Image} are not defined in \texttt{Wide\_Character}.

\texttt{Paragraphs 31 through 34 were moved to \texttt{Wide\_Wide\_Image}.}

{AI95-00285-01} The image of an integer value is the corresponding decimal literal, without underlines, leading zeros, exponent, or trailing spaces, but with a single leading character that is either a minus sign or a space.

**Implementation Note:** If the machine supports negative zeros for signed integer types, it is not specified whether "\texttt{0}" or "\texttt{0}" should be returned for negative zero. We don't have enough experience with such machines to know what is appropriate, and what other languages do. In any case, the implementation should be consistent.

{AI95-00285-01} The image of an enumeration value is either the corresponding identifier in upper case or the corresponding character literal (including the two apostrophes); neither leading nor trailing spaces are included. For a nongraphic character (a value of a character type that has no enumeration literal associated with it), the result is a corresponding language-defined or implementation-defined name in upper case (for example, the image of the nongraphic character identified as \texttt{nul} is “NUL”—the quotes are not part of the image).
Implementation Note: For an enumeration type T that has “holes” (caused by an
enumeration_representation_clause), T’Wide_Image should raise Program_Error if the value is one of the holes
(which is a bounded error anyway, since holes can be generated only via uninitialized variables and similar things).

{AI95-00285-01} The image of a floating-point value is a decimal real literal best
approximating the value (rounded away from zero if halfway between) with a single leading
caracter that is either a minus sign or a space, a single digit (that is nonzero unless the value
is zero), a decimal point, S’Digits – 1 (see 3.5.8) digits after the decimal point (but one if
S’Digits is one), an upper case E, the sign of the exponent (either + or –), and two or more
digits (with leading zeros if necessary) representing the exponent. If S’Signed_Zeros is True,
then the leading character is a minus sign for a negatively signed zero.

To be honest: Leading zeros are present in the exponent only if necessary to make the exponent at least two digits.

Reason: This image is intended to conform to that produced by Text_IO.Float_IO.Put in its default format.

Implementation Note: The rounding direction is specified here to ensure portability of output results.

{AI95-00285-01} The image of a fixed point value is a decimal real literal best
approximating the value (rounded away from zero if halfway between) with a single leading
character that is either a minus sign or a space, one or more digits before the decimal point
(with no redundant leading zeros), a decimal point, and S’Aft (see 3.5.10) digits after the
decimal point.

Reason: This image is intended to conform to that produced by Text_IO.Fixed_IO.Put.

Implementation Note: The rounding direction is specified here to ensure portability of output results.

Implementation Note: For a machine that supports negative zeros, it is not specified whether "–0.000" or "0.000" is
returned. See corresponding comment above about integer types with signed zeros.

S’Image function S’Image(Arg : S’Base) return String

{AI95-00285-01} {AI05-0264-1} The function returns an image of the value of Arg as a
String. The lower bound of the result is one. The image has the same sequence of graphic
caracters as that defined for S’Wide_Wide_Image if all the graphic characters
are defined in Character; otherwise, the sequence of characters is implementation defined (but
no shorter than that of S’Wide_Wide_Image for the same value of Arg).

Implementation defined: The sequence of characters of the value returned by S’Image when some of the graphic
caracters of S’Wide_Wide_Image are not defined in Character.

S’Wide_Wide_Width function S’Wide_Wide_Width(Arg : Wide_Wide_String) return S’Base

{AI95-00285-01} S’Wide_Wide_Width denotes the maximum length of a Wide_Wide_String
returned by S’Wide_Wide_Image over all values of the subtype S. It denotes zero for a
subtype that has a null range. Its type is universal_integer.

S’Wide_Width function S’Wide_Width(Arg : Wide/String) return S’Base

S’Wide_Width denotes the maximum length of a Wide_String returned by S’Wide_Image over all values of the subtype S. It denotes zero for a subtype that has a null range. Its type is universal_integer.

S’Width function S’Width(Arg : String) return S’Base

S’Width denotes the maximum length of a String returned by S’Image over all values of the subtype S. It denotes zero for a subtype that has a null range. Its type is universal_integer.

S’Wide_Wide_Value function S’Wide_Wide_Value(Arg : Wide_Wide_String) return S’Base

This function returns a value given an image of the value as a Wide_Wide_String, ignoring
any leading or trailing spaces.
For the evaluation of a call on S'Wide_Wide_Value for an enumeration subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an enumeration literal and if it corresponds to a literal of the type of S (or corresponds to the result of S'Wide_Wide_Image for a nongraphic character of the type), the result is the corresponding enumeration value; otherwise, Constraint_Error is raised.

Discussion: It's not crystal clear that Range_Check is appropriate here, but it doesn't seem worthwhile to invent a whole new check name just for this weird case, so we decided to lump it in with Range_Check.

To be honest: {8652/0096} {AI95-00053-01} A sequence of characters corresponds to the result of S'Wide_Wide_Image if it is the same ignoring case. Thus, the case of an image of a nongraphic character does not matter. For example, Character'Wide_Wide_Value("nul") does not raise Constraint_Error, even though Character'Wide_Wide_Image returns "NUL" for the nul character.

For the evaluation of a call on S'Wide_Wide_Value for an integer subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an integer literal, with an optional leading sign character (plus or minus for a signed type; only plus for a modular type), and the corresponding numeric value belongs to the base range of the type of S, then that value is the result; otherwise, Constraint_Error is raised.

Discussion: We considered allowing 'Value to return a representable but out-of-range value without a Constraint_Error. However, we currently require (see 4.9) in an assignment_statement like "X := <numeric_literal>;" that the value of the numeric-literal be in X's base range (at compile time), so it seems unfriendly and confusing to have a different range allowed for 'Value. Furthermore, for modular types, without the requirement for being in the base range, 'Value would have to handle arbitrarily long literals (since overflow never occurs for modular types).

For the evaluation of a call on S'Wide_Wide_Value for a real subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of one of the following:

- numeric_literal
- numeral[exponent]
- .numeral[exponent]
- base#.based_numeral.#[exponent]
- base#.based_numeral#

with an optional leading sign character (plus or minus), and if the corresponding numeric value belongs to the base range of the type of S, then that value is the result; otherwise, Constraint_Error is raised. The sign of a zero value is preserved (positive if none has been specified) if S'Signed_Zeros is True.

S'Wide_Value

S'Wide_Value denotes a function with the following specification:

```ada
function S'Wide_Value(Arg : Wide_String) return S'Base
```

This function returns a value given an image of the value as a Wide_String, ignoring any leading or trailing spaces.

{AI95-00285-01} {AI95-00264-1} For the evaluation of a call on S'Wide_Value for an enumeration subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an enumeration literal and if it corresponds to a literal of the type of S (or corresponds to the result of S'Wide_Image for a nongraphic character of the type), the result is the corresponding enumeration value; otherwise, Constraint_Error is raised.

For a numeric subtype S, the evaluation of a call on S'Wide_Value with Arg of type Wide_String is equivalent to a call on S'Wide_Value for a corresponding Arg of type Wide_Wide_String.
This paragraph was deleted. **Discussion:** It's not crystal clear that Range_Check is appropriate here, but it doesn't seem worthwhile to invent a whole new check name just for this weird case, so we decided to lump it in with Range_Check.

This paragraph was deleted. **To be honest:** {8652/0096} {A95-00053-01} A sequence of characters corresponds to the result of S'Wide_Image if it is the same ignoring case. Thus, the case of an image of a non-graphic character does not matter. For example, Character'Wide_Value("nul") does not raise Constraint_Error, even though Character'Wide_Image returns "NULL" for the null character.

**Reason:** S'Wide_Value is subtly different from S'Wide_Wide_Value for enumeration subtypes since S'Wide_Image might produce a different sequence of characters than S'Wide_Wide_Image if the enumeration literal uses characters outside of the predefined type Wide_Character. That is why we don't just define S'Wide_Value in terms of S'Wide_Wide_Value for enumeration subtypes. S'Wide_Value and S'Wide_Wide_Value for numeric subtypes yield the same result given the same sequence of characters.

**Paragraphs 44 through 51 were moved to Wide_Value.**

{A95-00285-01} For the evaluation of a call on S'Wide_Value (or S'Value) for an integer subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an integer literal, with an optional leading sign character (plus or minus for a signed type; only plus for a modular type), and the corresponding numeric value belongs to the base range of the type of S, then that value is the result; otherwise Constraint_Error is raised. **Discussion:** We considered allowing 'Value to return a representable but out of range value without a Constraint_Error. However, we currently require (see 4.9) in an assignment_statement like "X := <numeric_literal>;", that the value of the numeric literal be in X's base range (at compile time), so it seems unfriendly and confusing to have a different range allowed for 'Value. Furthermore, for modular types, without the requirement for being in the base range, 'Value would have to handle arbitrarily long literals (since overflow never occurs for modular types).

For the evaluation of a call on S'Wide_Value (or S'Value) for a real subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of one of the following:

- **numeric_literal**
- **numeral-[exponent]**
- **numeral[exponent]**
- **base#based_numeral.#[exponent]**
- **base#based_numeral#(exponent)**

with an optional leading sign character (plus or minus), and if the corresponding numeric value belongs to the base range of the type of S, then that value is the result; otherwise Constraint_Error is raised. The sign of a zero value is preserved (positive if none has been specified) if S'Signed_Zeros is True. **Reason:** S'Value is subtly different from S'Wide_Wide_Value for enumeration subtypes; see the discussion under S'Wide_Value since S'Image might produce a different sequence of characters than...
S'Wide_Image if the enumeration literal uses characters outside of the predefined type Character. That is why we don't just define S'Value in terms of S'Wide_Value for enumeration subtypes. S'Value and S'Wide_Value for numeric subtypes yield the same result given the same sequence of characters.

**Implementation Permissions**

{AI95-00285-01} An implementation may extend the **Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, and Image** attributes of a floating point type to support special values such as infinities and NaNs.

**Proof:** {AI95-00285-01} The permission is really only necessary for **Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, and Image** defined in terms of **Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, and Image** and because the behavior of **Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, and Image** is already unspecified for things like infinities and NaNs.

**Reason:** This is to allow implementations to define full support for IEEE arithmetic. See also the similar permission for Get in A.10.9.

{AI05-0182-1} {AI05-0262-1} {AI05-0269-1} An implementation may extend the **Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, and Value** attributes of a character type to accept strings of the form “Hex $$\text{hhhhhhhh}$$” (ignoring case) for any character (not just the ones for which **Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, Wide_Value, and Image** would produce that form — see 3.5.2), as well as three-character strings of the form “'$$X$$'”, where $$X$$ is any character, including non-graphic characters.

**Static Semantics**

{AI05-0228-1} For a scalar type, the following language-defined representation aspect may be specified with an **aspect specification** (see 13.1.1):

**Default_Value**

This aspect shall be specified by a static expression, and that expression shall be explicit, even if the aspect has a boolean type. **Default_Value** shall be specified only on a **full_type_declaration**.

**Reason:** The part about requiring an explicit expression is to disallow omitting the value for this aspect, which would otherwise be allowed by the rules of 13.1.1.

This is a representation aspect in order to disallow specifying it on a derived type that has inherited primitive subprograms: that is necessary as the sizes of **out** parameters could be different whether or not a **Default_Value** is specified (see 6.4.1).

**Aspect Description for Default_Value:** **Default_value** for a scalar subtype.

{AI05-0228-1} If a derived type with no primitive subprograms inherits a boolean **Default_Value** aspect, the aspect may be specified to have any value for the derived type.

**Reason:** This overrides the 13.1.1 rule that says that a boolean aspect with a value **True** cannot be changed.

**Name Resolution Rules**

{AI05-0228-1} The expected type for the expression specified for the **Default_Value** aspect is the type defined by the **full_type_declaration** on which it appears.

**NOTES**

24 The evaluation of S'First or S'Last never raises an exception. If a scalar subtype S has a nonnull range, S'First and S'Last belong to this range. These values can, for example, always be assigned to a variable of subtype S.

**Discussion:** This paragraph addresses an issue that came up with Ada 83, where for fixed point types, the end points of the range specified in the type definition were not necessarily within the base range of the type. However, it was later clarified (and we reconfirm it in 3.5.9, “Fixed Point Types”) that the First and Last attributes reflect the true bounds chosen for the type, not the bounds specified in the type definition (which might be outside the ultimately chosen base range).

25 For a subtype of a scalar type, the result delivered by the attributes Succ, Pred, and Value might not belong to the subtype; similarly, the actual parameters of the attributes Succ, Pred, and Image need not belong to the subtype.

13 December 2012
For any value \(V\) (including any nongraphic character) of an enumeration subtype \(S\), \(S'\text{Value}(S'\text{Image}(V))\) equals \(V\), as does \(S'\text{Wide Value}(S'\text{Wide Image}(V))\) and \(S'\text{Wide Wide Value}(S'\text{Wide Wide Image}(V))\). None of these expressions ever raises \Constraint{Error}.

**Examples**

**Examples of ranges:**

```
-10 .. 10
X .. X + 1
0.0 .. 2.0*Pi
Red .. Green  -- see 3.5.1
1 .. 0        -- a null range
Table'Range    -- a range attribute reference (see 3.6)
```

**Examples of range constraints:**

```
range -999.0 .. +999.0
range S'First+1 .. S'Last-1
```

**Incompatibilities With Ada 83**

63.a/1 S'Base is no longer defined for nonscalar types. One conceivable existing use of S'Base for nonscalar types is S'Base'Size where S is a generic formal private type. However, that is not generally useful because the actual subtype corresponding to S might be a constrained array or discriminated type, which would mean that S'Base'Size might very well overflow (for example, S'Base'Size where S is a constrained subtype of String will generally be 8 * (Integer'Last + 1)). For derived discriminated types that are packed, S'Base'Size might not even be well defined if the first subtype is constrained, thereby allowing some amount of normally required “dope” to have been squeezed out in the packing. Hence our conclusion is that S'Base'Size is not generally useful in a generic, and does not justify keeping the attribute Base for nonscalar types just so it can be used as a prefix.

**Extensions to Ada 83**

The attribute S'Base for a scalar subtype is now permitted anywhere a subtype_mark is permitted. S'Base'First .. S'Base'Last is the base range of the type. Using an attribute_definition_clause, one cannot specify any subtype-specific attributes for the subtype denoted by S'Base (the base subtype).

The attribute S'Range is now allowed for scalar subtypes.

The attributes S'Min and S'Max are now defined, and made available for all scalar types.

The attributes S'Succ, S'Pred, S'Image, S'Value, and S'Width are now defined for real types as well as discrete types.

Wide_String versions of S'Image and S'Value are defined. These are called S'Wide_Image and S'Wide_Value to avoid introducing ambiguities involving uses of these attributes with string literals.

**Wording Changes from Ada 83**

We now use the syntactic category range_attribute_reference since it is now syntactically distinguished from other attribute references.

The definition of S'Base has been moved here from 3.3.3 since it now applies only to scalar types.

More explicit rules are provided for nongraphic characters.

**Extensions to Ada 95**

63.j/2 The attributes Wide_Wide_Image, Wide_Wide_Value, and Wide_Wide_Width are new. Note that Wide_Image and Wide_Value are now defined in terms of Wide_Wide_Image and Wide_Wide_Value, but the image of types other than characters have not changed.

**Wording Changes from Ada 95**

63.k/2 The Wide_Image and Wide_Value attributes are now defined in terms of Wide_Wide_Image and Wide_Wide_Value, but the images of numeric types have not changed.

**Inconsistencies With Ada 2005**

63.l/3 **Correction:** Soft hyphen (code point 173) is nongraphic in ISO/IEC 10646:2011 (and also in the 2003 version of that standard). Thus, we have given it the language-defined name soft_hyphen. This changes the result of Character'Image (and all of the related types and Image attributes) for this character, and changes the behavior of Character'Value (and all of the related types and Value attributes) for this character, and (in unusual circumstances),...
changes the result for Character'Width (and all of the related types and Width attributes). The vast majority of programs won’t see any difference, as they are already prepared to handle non-graphic characters.

**Correction:** Added an Implementation Permissions to let Wide_Value, Wide_Value, and Value accept strings in the form of literals containing non-graphic characters and "Hex_hhhhhhh" for Latin-1 and graphic characters. These were required to raise Constraint_Error in Ada 2005. Since these attributes aren’t very useful, implementations were inconsistent as to whether these were accepted, and since code that would care why the attribute failed seems unlikely, this should not be a problem in practice.

**Extensions to Ada 2005**

**AI05-0228-1** The new aspect Default_Value allows defining implicit initial values (see 3.3.1) for scalar types.

### 3.5.1 Enumeration Types

[An enumeration_type_definition defines an enumeration type.]

**Syntax**

```ada
enumeration_type_definition ::= 
  (enumeration_literal_specification {, enumeration_literal_specification}) 
enumeration_literal_specification ::= defining_identifier | defining_character_literal 
defining_character_literal ::= character_literal
```

**Legality Rules**

**AI05-0227-1** **AI05-0299-1** The defining_identifiers in upper case [and the defining_character_literals] listed in an enumeration_type_definition shall be distinct.

Proof: **AI05-0227-1** For character literals, this is a ramification of the normal disallowance of homographs explicitly declared immediately in the same declarative region.

Reason: **AI05-0227-1** To ease implementation of the attribute Wide_Wide_Value, we require that all enumeration literals have distinct images.

**Static Semantics**

**AI05-0006-1** Each enumeration_literal_specification is the explicit declaration of the corresponding enumeration literal: it declares a parameterless function, whose defining name is the defining_identifier or defining_character_literal, and whose result subtype is the base subtype of the enumeration type.

Reason: This rule defines the profile of the enumeration literal, which is used in the various types of conformance.

Ramification: The parameterless function associated with an enumeration literal is fully defined by the enumeration_type_definition; a body is not permitted for it, and it never fails the Elaboration_Check when called.

Discussion: **AI05-0006-1** The result subtype is primarily a concern when an enumeration literal is used as the expression of a case statement, due to the full coverage requirement based on the nominal subtype.

Each enumeration literal corresponds to a distinct value of the enumeration type, and to a distinct position number. The position number of the value of the first listed enumeration literal is zero; the position number of the value of each subsequent enumeration literal is one more than that of its predecessor in the list.

[The predefined order relations between values of the enumeration type follow the order of corresponding position numbers.]

[If the same defining_identifier or defining_character_literal is specified in more than one enumeration_type_definition, the corresponding enumeration literals are said to be overloaded. At any place where an overloaded enumeration literal occurs in the text of a program, the type of the enumeration literal has to be determinable from the context (see 8.6).]
Dynamic Semantics

The elaboration of an enumeration_type_definition creates the enumeration type and its first subtype, which is constrained to the base range of the type.

Ramification: The first subtype of a discrete type is always constrained, except in the case of a derived type whose parent subtype is Whatever'Base.

When called, the parameterless function associated with an enumeration literal returns the corresponding value of the enumeration type.

NOTES
27 If an enumeration literal occurs in a context that does not otherwise suffice to determine the type of the literal, then qualification by the name of the enumeration type is one way to resolve the ambiguity (see 4.7).

Examples

type Day is (Mon, Tue, Wed, Thu, Fri, Sat, Sun);
type Suit is (Clubs, Diamonds, Hearts, Spades);
type Gender is (M, F);
type Level is (Low, Medium, Urgent);
type Color is (White, Red, Yellow, Green, Blue, Brown, Black);
type Light is (Red, Amber, Green); -- Red and Green are overloaded

type Hexa is ('A', 'B', 'C', 'D', 'E', 'F');
type Mixed is ('A', 'B', '*', B, None, '?', '%');
subtype Weekday is Day range Mon .. Fri;
subtype Major is Suit range Hearts .. Spades;
subtype Rainbow is Color range Red .. Blue; -- the Color Red, not the Light

3.5.2 Character Types

Static Semantics

An enumeration type is said to be a character type if at least one of its enumeration literals is a character_literal.

The predefined type Character is a character type whose values correspond to the 256 code points of Row 00 (also known as Latin-1) of the ISO/IEC 10646 ISO/IEC 10646 Basic Multilingual Plane (BMP). Each of the graphic characters of Row 00 of the BMP has a corresponding character_literal in Character. Each of the non-graphics positions of Row 00 (0000-001F and 007F-009F) has a corresponding language-defined name, which is not usable as an enumeration literal, but which is usable with the attributes Image.
Wide_Image, Wide_Wide_Image, Value, Wide_Value, and Wide_Wide_Value; these names are given in the definition of type Character in A.1, “The Package Standard”, but are set in italics.

{AI95-00285-01} {AI05-0262-1} The predefined type Wide_Character is a character type whose values correspond to the 65536 code points of the ISO/IEC 10646:2011 Basic Multilingual Plane (BMP). Each of the graphic characters of the BMP has a corresponding character literal in Wide_Character. The first 256 values of Wide_Character have the same character literal or language-defined name as defined for Character. Each of the graphic characters has The last 2 values of Wide_Character correspond to the nongraphic positions FFFE and FFFF of the BMP, and are assigned the language-defined names FFFE and FFFF. As with the other language-defined names for nongraphic characters, the names FFFE and FFFF are usable only with the attributes (Wide_)Image and (Wide_)Value; they are not usable as enumeration literals. All other values of Wide_Character are considered graphic characters, and have a corresponding character literal.

{AI95-00285-01} {AI05-0262-1} The predefined type Wide_Wide_Character is a character type whose values correspond to the 2147483648 code points of the ISO/IEC 10646:2011 character set. Each of the graphic characters has a corresponding character literal in Wide_Wide_Character. The first 65536 values of Wide_Wide_Character have the same character literal or language-defined name as defined for Wide_Character.

{AI95-00285-01} {AI05-0262-1} The characters whose code point is larger than 16#FF# and which are not graphic characters have language-defined names which are formed by appending to the string "Hex_" the representation of their code point in hexadecimal as eight extended digits. As with other language-defined names, these names are usable only with the attributes (Wide_)Wide_Image and (Wide_)Wide_Value; they are not usable as enumeration literals.

Reason: {AI95-00285-01} The language-defined names are not usable as enumeration literals to avoid "polluting" the name space. Since Wide_Character and Wide_Wide_Character are defined in Standard, if the language-defined names FFFE and FFFF were usable as enumeration literals, they would hide other nonoverloadable declarations with the same names in used packages.]

{AI95-00285-01} ISO 10646 has not defined the meaning of all of the code positions from 0100 through FFFD, but they are all considered graphic characters by Ada to simplify the implementation, and to allow for revisions to ISO 10646. In ISO 10646, FFFE and FFFF are special, and will never be associated with graphic characters in any revision.

Implementation Permissions

{AI95-00285-01} In a nonstandard mode, an implementation may provide other interpretations for the predefined types Character and Wide_Character[, to conform to local conventions]. Paragraphs 6 and 7 were deleted.

Implementation Advice

{AI95-00285-01} If an implementation supports a mode with alternative interpretations for Character and Wide_Character, the set of graphic characters of Character should nevertheless remain a proper subset of the set of graphic characters of Wide_Character. Any character set “localizations” should be reflected in the results of the subprograms defined in the language-defined package Characters.Handling (see A.3) available in such a mode. In a mode with an alternative interpretation of Character, the implementation should also support a corresponding change in what is a legal identifier letter.

NOTES

28 The language-defined library package Characters.Latin_1 (see A.3.3) includes the declaration of constants denoting control characters, lower case characters, and special characters of the predefined type Character.
To be honest: The package ASCII does the same, but only for the first 128 characters of Character. Hence, it is an obsolescent package, and we no longer mention it here.

A conventional character set such as EBCDIC can be declared as a character type; the internal codes of the characters can be specified by an enumeration_representation_clause as explained in subclause clause 13.4.

Example of a character type:

```ada
type Roman_Digit is ('I', 'V', 'X', 'L', 'C', 'D', 'M');
```

The declaration of Wide_Character in package Standard hides use-visible declarations with the same defining identifier. In the unlikely event that an Ada 83 program had depended on such a use-visible declaration, and the program remains legal after the substitution of Standard.Wide_Character, the meaning of the program will be different.

The presence of Wide_Character in package Standard means that an expression such as

```
'a' = 'b'
```

is ambiguous in Ada 95, whereas in Ada 83 both literals could be resolved to be of type Character.

The change in visibility rules (see 4.2) for character literals means that additional qualification might be necessary to resolve expressions involving overloaded subprograms and character literals.

The type Character has been extended to have 256 positions, and the type Wide_Character has been added. Note that this change was already approved by the ARG for Ada 83 conforming compilers.

The rules for referencing character literals are changed (see 4.2), so that the declaration of the character type need not be directly visible to use its literals, similar to null and string literals. Context is used to resolve their type.

The declaration of Wide_Wide_Character in package Standard hides use-visible declarations with the same defining identifier. In the (very) unlikely event that an Ada 95 program had depended on such a use-visible declaration, and the program remains legal after the substitution of Standard.Wide_Wide_Character, the meaning of the program will be different.

Characters are now defined in terms of the entire ISO/IEC 10646:2003 character set.

We dropped the Implementation Advice for nonstandard interpretation of character sets; an implementation can do what it wants in a nonstandard mode, so there isn't much point to any advice.
3.5.3 Boolean Types

Static Semantics

There is a predefined enumeration type named Boolean, [declared in the visible part of package Standard]. It has the two enumeration literals False and True ordered with the relation False < True. Any descendant of the predefined type Boolean is called a boolean type.

Implementation Note: An implementation is not required to support enumeration representation clauses on boolean types that impose an unacceptable implementation burden. See 13.4, “Enumeration Representation Clauses”. However, it is generally straightforward to support representations where False is zero and True is 2**n – 1 for some n.

3.5.4 Integer Types

An integer_type_definition defines an integer type; it defines either a signed integer type, or a modular integer type. The base range of a signed integer type includes at least the values of the specified range. A modular type is an integer type with all arithmetic modulo a specified positive modulus; such a type corresponds to an unsigned type with wrap-around semantics.

Syntax

integer_type_definition ::= signed_integer_type_definition | modular_type_definition

signed_integer_type_definition ::= range static_simple_expression .. static_simple_expression

Discussion: We don't call this a range_constraint, because it is rather different — not only is it required to be static, but the associated overload resolution rules are different than for normal range constraints. A similar comment applies to real_range_specification. This used to be integer_range_specification but when we added support for modular types, it seemed overkill to have three levels of syntax rules, and just calling these signed_integer_range_specification and modular_range_specification loses the fact that they are defining different classes of types, which is important for the generic type matching rules.

modular_type_definition ::= mod static_expression

Name Resolution Rules

Each simple_expression in a signed_integer_type_definition is expected to be of any integer type; they need not be of the same type. The expression in a modular_type_definition is likewise expected to be of any integer type.

Legality Rules

The simple_expressions of a signed_integer_type_definition shall be static, and their values shall be in the range System.Min_Int .. System.Max_Int.

The expression of a modular_type_definition shall be static, and its value (the modulus) shall be positive, and shall be no greater than System.Max_Binary_Modulus if a power of 2, or no greater than System.Max_Nonbinary_Modulus if not.

Reason: For a 2's-complement machine, supporting nonbinary moduli greater than System.Max_Int can be quite difficult, whereas essentially any binary moduli are straightforward to support, up to 2*System.Max_Int+2, so this justifies having two separate limits.
The set of values for a signed integer type is the (infinite) set of mathematical integers[, though only values of the base range of the type are fully supported for run-time operations]. The set of values for a modular integer type are the values from 0 to one less than the modulus, inclusive.

A signed_integer_type_definition defines an integer type whose base range includes at least the values of the simple_expressions and is symmetric about zero, excepting possibly an extra negative value. A signed_integer_type_definition also defines a constrained first subtype of the type, with a range whose bounds are given by the values of the simple_expressions, converted to the type being defined.

Implementation Note: {AI95-00114-01} The base range of a signed integer type might be much larger than is necessary to satisfy the aboveaboued requirements.

To be honest: The conversion mentioned above is not an implicit subtype conversion (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type).

A modular_type_definition defines a modular type whose base range is from zero to one less than the given modulus. A modular_type_definition also defines a constrained first subtype of the type with a range that is the same as the base range of the type.

There is a predefined signed integer subtype named Integer[, declared in the visible part of package Standard]. It is constrained to the base range of its type.

Reason: Integer is a constrained subtype, rather than an unconstrained subtype. This means that on assignment to an object of subtype Integer, a range check is required. On the other hand, an object of subtype IntegerBase is unconstrained, and no range check (only overflow check) is required on assignment. For example, if the object is held in an extended-length register, its value might be outside of Integer'First .. Integer'Last. All parameter and result subtypes of the predefined integer operators are of such unconstrained subtypes, allowing extended-length registers to be used as operands or for the result. In an earlier version of Ada 95, Integer was unconstrained. However, the fact that certain Constraint_Errors might be omitted or appear elsewhere was felt to be an undesirable upward inconsistency in this case. Note that for Float, the opposite conclusion was reached, partly because of the high cost of performing range checks when not actually necessary. Objects of subtype Float are unconstrained, and no range checks, only overflow checks, are performed for them.

Integer has two predefined subtypes, [declared in the visible part of package Standard:]

<table>
<thead>
<tr>
<th>Subtype</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Natural</td>
<td>is Integer range 0 .. Integer'Last;</td>

</tbody>
</table>

A type defined by an integer_type_definition is implicitly derived from root_integer, an anonymous predefined (specific) integer type, whose base range is System.Min_Int .. System.Max_Int. However, the base range of the new type is not inherited from root_integer, but is instead determined by the range or modulus specified by the integer_type_definition. [Integer literals are all of the type universal_integer, the universal type (see 3.4.1) for the class rooted at root_integer, allowing their use with the operations of any integer type.]

Discussion: This implicit derivation is not considered exactly equivalent to explicit derivation via a derived_type_definition. In particular, integer types defined via a derived_type_definition inherit their base range from their parent type. A type defined by an integer_type_definition does not necessarily inherit its base range from root_integer. It is not specified whether the implicit derivation from root_integer is direct or indirect, not that it really matters. All we want is for all integer types to be descendants of root_integer.

\{8652/0099\} {AI95-00152-01} Note that this derivation does not imply any inheritance of subprograms. Subprograms are inherited only for types derived by a derived_type_definition (see 3.4), or a private_extension_declaration (see 7.3, 7.3.1, and 12.5.1).

Implementation Note: It is the intent that even nonstandard integer types (see below) will be descendants of root_integer, even though they might have a base range that exceeds that of root_integer. This causes no problem for static calculations, which are performed without range restrictions (see 4.9). However for run-time calculations, it is possible that Constraint_Error might be raised when using an operator of root_integer on the result of 'Val applied to a value of a nonstandard integer type.

The position number of an integer value is equal to the value.
For every modular subtype S, the following attributes are defined:

\( S'Mod \)

\( S'Mod \) denotes a function with the following specification:

```ada
function S'Mod (Arg : universal_integer) return S'Base
```

This function returns \( Arg \mod S'Modulus \), as a value of the type of \( S \).

\( S'Modulus \)

\( S'Modulus \) yields the modulus of the type of \( S \), as a value of the type \( universal_integer \).

Dynamic Semantics

The elaboration of an integer_type_definition creates the integer type and its first subtype.

For a modular type, if the result of the execution of a predefined operator (see 4.5) is outside the base range of the type, the result is reduced modulo the modulus of the type to a value that is within the base range of the type.

For a signed integer type, the exception Constraint_Error is raised by the execution of an operation that cannot deliver the correct result because it is outside the base range of the type. [For any integer type, Constraint_Error is raised by the operators "/", "rem", and "mod" if the right operand is zero.]

Implementation Requirements

In an implementation, the range of Integer shall include the range \(-2^{15}+1..+2^{15}-1\).

If Long_Integer is predefined for an implementation, then its range shall include the range \(-2^{31}+1..+2^{31}-1\).

System.Max_Binary_Modulus shall be at least \( 2^{16} \).

Implementation Permissions

For the execution of a predefined operation of a signed integer type, the implementation need not raise Constraint_Error if the result is outside the base range of the type, so long as the correct result is produced.

Discussion: Constraint_Error is never raised for operations on modular types, except for divide-by-zero (and rem/mod-by-zero).

An implementation may provide additional predefined signed integer types[, declared in the visible part of Standard], whose first subtypes have names of the form Short_Integer, Long_Integer, Short_Short_Integer, Long_Long_Integer, etc. Different predefined integer types are allowed to have the same base range. However, the range of Integer should be no wider than that of Long_Integer. Similarly, the range of Short_Integer (if provided) should be no wider than Integer. Corresponding recommendations apply to any other predefined integer types. There need not be a named integer type corresponding to each distinct base range supported by an implementation. The range of each first subtype should be the base range of its type.

Implementation defined: The predefined integer types declared in Standard.

An implementation may provide nonstandard integer types, descendants of root_integer that are declared outside of the specification of package Standard, which need not have all the standard characteristics of a type defined by an integer_type_definition. For example, a nonstandard integer type might have an asymmetric base range or it might not be allowed as an array or loop index (a very long integer). Any type descended from a nonstandard integer type is also nonstandard. An implementation may place arbitrary restrictions on the use of such types; it is implementation defined whether operators that are predefined for “any integer type” are defined for a particular nonstandard integer type. [In any case, such types are not permitted as explicit_generic_actual_parameters for formal scalar types — see 12.5.2.]
An implementation should support Long_Integer in addition to Integer if the target machine supports 32-bit (or longer) arithmetic. No other named integer subtypes are recommended for package Standard. Instead, appropriate named integer subtypes should be provided in the library package Interfaces (see B.2).

Implementation Advice:
Long_Integer should be declared in Standard if the target supports 32-bit arithmetic. No other named integer subtypes should be declared in Standard.

Implementation Note: To promote portability, implementations should explicitly declare the integer (sub)types Integer and Long_Integer in Standard, and leave other predefined integer types anonymous. For implementations that already support Byte_Integer, etc., upward compatibility argues for keeping such declarations in Standard during the transition period, but perhaps generating a warning on use. A separate package Interfaces in the predefined environment is available for pre-declaring types such as Integer_8, Integer_16, etc. See B.2. In any case, if the user declares a subtype (first or not) whose range fits in, for example, a byte, the implementation can store variables of the subtype in a single byte, even if the base range of the type is wider.

An implementation for a two's complement machine should support modular types with a binary modulus up to System.Max_Int*2+2. An implementation should support a nonbinary modulus up to Integer'Last.

Implementation Advice: For a two's complement target, modular types with a binary modulus up to System.Max_Int*2+2 should be supported. A nonbinary modulus up to Integer'Last should be supported.

Reason: Modular types provide bit-wise "and", "or", "xor", and "not" operations. It is important for systems programming that these be available for all integer types of the target hardware.

Ramification: Note that on a one's complement machine, the largest supported modular type would normally have a nonbinary modulus. On a two's complement machine, the largest supported modular type would normally have a binary modulus.

Implementation Note: Supporting a nonbinary modulus greater than Integer'Last can impose an undesirable implementation burden on some machines.

NOTES
30 Integer literals are of the anonymous predefined integer type universal_integer. Other integer types have no literals. However, the overload resolution rules (see 8.6, "The Context of Overload Resolution") allow expressions of the type universal_integer whenever an integer type is expected.

31 The same arithmetic operators are predefined for all signed integer types defined by a signed_integer_type_definition (see 4.5, "Operators and Expression Evaluation"). For modular types, these same operators are predefined, plus bit-wise logical operators (and, or, xor, and not). In addition, for the unsigned types declared in the language-defined package Interfaces (see B.2), functions are defined that provide bit-wise shifting and rotating.

32 Modular types match a generic_formal_parameter_declaration of the form "type T is mod <>;"; signed integer types match "type T is range <>;" (see 12.5.2).

Examples

Examples of integer types and subtypes:

```ada
34 type Page_Num is range 1 .. 2_000;
type Line_Size is range 1 .. Max_Line_Size;
```
An implementation is allowed to support any number of distinct base ranges for integer types, even if fewer integer types are explicitly declared in Standard.

Modular (unsigned, wrap-around) types are new.

Ada 83's integer types are now called "signed" integer types, to contrast them with "modular" integer types.

Standard.Integer, Standard.Long_Integer, etc., denote constrained subtypes of predefined integer types, consistent with the Ada 95 model that only subtypes have names.

We now impose minimum requirements on the base range of Integer and Long_Integer.

We no longer explain integer type definition in terms of an equivalence to a normal type derivation, except to say that all integer types are by definition implicitly derived from root_integer. This is for various reasons.

First of all, the equivalence with a type derivation and a subtype declaration was not perfect, and was the source of various AIs (for example, is the conversion of the bounds static? Is a numeric type a derived type with respect to other rules of the language?)

Secondly, we don't want to require that every integer size supported shall have a corresponding named type in Standard. Adding named types to Standard creates nonportabilities.

Thirdly, we don't want the set of types that match a formal derived type "type T is new Integer;" to depend on the particular underlying integer representation chosen to implement a given user-defined integer type. Hence, we would have needed anonymous integer types as parent types for the implicit derivation anyway. We have simply chosen to identify only one anonymous integer type — root_integer, and stated that every integer type is derived from it.

Finally, the “fiction” that there were distinct preexisting predefined types for every supported representation breaks down for fixed point with arbitrary smalls, and was never exploited for enumeration types, array types, etc. Hence, there seems little benefit to pushing an explicit equivalence between integer type definition and normal type derivation.

The Mod attribute is new. It eases mixing of signed and unsigned values in an expression, which can be difficult as there may be no type which can contain all of the values of both of the types involved.

Corrigendum: Added additional permissions for modular types on one's complement machines.

### 3.5.5 Operations of Discrete Types

#### Static Semantics

For every discrete subtype S, the following attributes are defined:

**S'Pos**

S'Pos denotes a function with the following specification:

```ada
function S'Pos (Arg : S'Base) return universal_integer
```

This function returns the position number of the value of Arg, as a value of type universal_integer.

**S'Val**

S'Val denotes a function with the following specification:

```ada
function S'Val (Arg : universal_integer) return S'Base
```
This function returns a value of the type of S whose position number equals the value of \textit{Arg}.
For the evaluation of a call on S'Val, if there is no value in the base range of its type with the
given position number, Constraint\_Error is raised.

\textbf{Ramification:} By the overload resolution rules, a formal parameter of type \textit{universal_integer} allows an actual parameter of any integer type.

\textbf{Reason:} We considered allowing S'Val for a signed integer subtype S to return an out-of-range value, but since checks were required for enumeration and modular types anyway, the allowance didn't seem worth the complexity of the rule.

\{AI05-0297-1\} For every static discrete subtype S for which there exists at least one value belonging to S that satisfies any predicate of S, the following attributes are defined:

\textbf{S'First\_Valid} \{AI05-0297-1\} S'First\_Valid denotes the smallest value that belongs to S and satisfies the predicate of S. The value of this attribute is of the type of S.

\textbf{S'Last\_Valid} \{AI05-0297-1\} S'Last\_Valid denotes the largest value that belongs to S and satisfies the predicate of S. The value of this attribute is of the type of S.

\{AI05-0297-1\} \textbf{First\_Valid and Last\_Valid attribute references are always static expressions. Any explicit predicate of S can only have been specified by a Static Predicate aspect.}\]

\textbf{Proof:} An attribute\_reference is static if the prefix is a static subtype (see 4.9), (true by definition) and any arguments are static (there are none). Similarly, a dynamic predicate always makes a subtype nonstatic. QED.

\textbf{Reason:} We require there to be at least one value so that these are always values of the subtype. (This sidesteps the question of what to return for a subtype with no values.)

\textbf{Discussion:} These attributes are intended primarily for use in the case where the Static Predicate aspect of S has been specified; First and Last are equivalent if these are allowed and there is no predicate.

\textbf{Implementation Advice}

For the evaluation of a call on S'Pos for an enumeration subtype, if the value of the operand does not correspond to the internal code for any enumeration literal of its type \{perhaps due to an uninitialized variable\}, then the implementation should raise Program\_Error. This is particularly important for enumeration types with noncontiguous internal codes specified by an \textit{enumeration_representation_-clause}.

\textbf{Implementation Advice:} Program\_Error should be raised for the evaluation of S'Pos for an enumeration type, if the value of the operand does not correspond to the internal code for any enumeration literal of the type.

\textbf{Reason:} We say Program\_Error here, rather than Constraint\_Error, because the main reason for such values is uninitialized variables, and the normal way to indicate such a use (if detected) is to raise Program\_Error. (Other reasons would involve the misuse of low-level features such as Unchecked\_Conversion.)

NOTES

33 Indexing and loop iteration use values of discrete types.

10/3 \{AI05-0299-1\} The predefined operations of a discrete type include the assignment operation, qualification, the membership tests, and the relational operators; for a boolean type they include the short-circuit control forms and the logical operators; for an integer type they include type conversion to and from other numeric types, as well as the binary and unary adding operators -- and +, the multiplying operators, the unary operator \textbf{abs}, and the exponentiation operator. The assignment operation is described in 5.2. The other predefined operations are described in Clause Section 4.

35 As for all types, objects of a discrete type have Size and Address attributes (see 13.3).

36 For a subtype of a discrete type, the result delivered by the attribute Val might not belong to the subtype; similarly, the actual parameter of the attribute Pos need not belong to the subtype. The following relations are satisfied (in the absence of an exception) by these attributes:

\begin{align*}
\text{S'Val(S'Pos(X))} &= X \\
\text{S'Pos(S'Val(N))} &= N
\end{align*}
Examples of attributes of discrete subtypes:

- For the types and subtypes declared in subclause 3.5.1 the following hold:
- Color'First = White, Color'Last = Black
- Rainbow'First = Red, Rainbow'Last = Blue
- Color'Succ(Blue) = Rainbow'Succ(Blue) = Brown
- Color'Pos(Blue) = Rainbow'Pos(Blue) = 4
- Color'Val(0) = Rainbow'Val(0) = White

Extensions to Ada 83

The attributes S’Succ, S’Pred, S’Width, S’Image, and S’Value have been generalized to apply to real types as well (see 3.5, “Scalar Types”).

Extensions to Ada 2005

{AI05-0297-1} The attributes S'First_Valid and S'Last_Valid are new.

3.5.6 Real Types

Real types provide approximations to the real numbers, with relative bounds on errors for floating point types, and with absolute bounds for fixed point types.

Syntax

real_type_definition ::= floating_point_definition | fixed_point_definition

Static Semantics

A type defined by a real_type_definition is implicitly derived from root_real, an anonymous predefined (specific) real type. [Hence, all real types, whether floating point or fixed point, are in the derivation class rooted at root_real.]

Ramification: It is not specified whether the derivation from root_real is direct or indirect, not that it really matters. All we want is for all real types to be descendants of root_real.

{8652/0099} {AI05-00152-01} Note that this derivation does not imply any inheritance of subprograms. Subprograms are inherited only for types derived by a derived_type_definition (see 3.4), or a private_extension_declaration (see 7.3, 7.3.1, and 12.5.1).

[ Real literals are all of the type universal_real, the universal type (see 3.4.1) for the class rooted at root_real, allowing their use with the operations of any real type. Certain multiplying operators have a result type of universal_fixed (see 4.5.5), the universal type for the class of fixed point types, allowing the result of the multiplication or division to be used where any specific fixed point type is expected.]

Dynamic Semantics

The elaboration of a real_type_definition consists of the elaboration of the floating_point_definition or the fixed_point_definition.

Implementation Requirements

An implementation shall perform the run-time evaluation of a use of a predefined operator of root_real with an accuracy at least as great as that of any floating point type definable by a floating_point_definition.

Ramification: Static calculations using the operators of root_real are exact, as for all static calculations. See 4.9.

Implementation Note: The Digits attribute of the type used to represent root_real at run time is at least as great as that of any other floating point type defined by a floating_point_definition, and its safe range includes that of any such
floating point type with the same Digits attribute. On some machines, there might be real types with less accuracy but a wider range, and hence run-time calculations with root_real might not be able to accommodate all values that can be represented at run time in such floating point or fixed point types.

Implementation Permissions

\{AI95-00114-01\} [For the execution of a predefined operation of a real type, the implementation need not raise Constraint_Error if the result is outside the base range of the type, so long as the correct result is produced, or the Machine_Overflows attribute of the type is False (see G.2).]

An implementation may provide nonstandard real types, descendants of root_real that are declared outside of the specification of package Standard, which need not have all the standard characteristics of a type defined by a real_type_definition. For example, a nonstandard real type might have an asymmetric or unsigned base range, or its predefined operations might wrap around or “saturate” rather than overflow (modular or saturating arithmetic), or it might not conform to the accuracy model (see G.2). Any type descended from a nonstandard real type is also nonstandard. An implementation may place arbitrary restrictions on the use of such types; it is implementation defined whether operators that are predefined for “any real type” are defined for a particular nonstandard real type. [In any case, such types are not permitted as explicit_generic_actual_parameters for formal scalar types — see 12.5.2.]

Implementation defined: Any nonstandard real types and the operators defined for them.

NOTES

37 As stated, real literals are of the anonymous predefined real type universal_real. Other real types have no literals. However, the overload resolution rules (see 8.6) allow expressions of the type universal_real whenever a real type is expected.

Wording Changes from Ada 83

9.a The syntax rule for real_type_definition is modified to use the new syntactic categories floating_point_definition and fixed_point_definition, instead of floating_point_constraint and fixed_point_constraint, because the semantics of a type definition are significantly different than the semantics of a constraint.

9.b All discussion of model numbers, safe ranges, and machine numbers is moved to 3.5.7, 3.5.8, and G.2. Values of a fixed point type are now described as being multiples of the small of the fixed point type, and we have no need for model numbers, safe ranges, etc. for fixed point types.

3.5.7 Floating Point Types

For floating point types, the error bound is specified as a relative precision by giving the required minimum number of significant decimal digits.

Syntax

floating_point_definition ::= 
  digits static_expression [real_range_specification]
real_range_specification ::= 
  range static_simple_expression .. static_simple_expression

Name Resolution Rules

4 The requested decimal precision, which is the minimum number of significant decimal digits required for the floating point type, is specified by the value of the expression given after the reserved word digits. This expression is expected to be of any integer type.

5 Each simple_expression of a real_range_specification is expected to be of any real type[; the types need not be the same].
Legality Rules

The requested decimal precision shall be specified by a static expression whose value is positive and no greater than System.Max_Base_Digits. Each simple_expression of a real_range_specification shall also be static. If the real_range_specification is omitted, the requested decimal precision shall be no greater than System.Max_Digits.

Reason: We have added Max_Base_Digits to package System. It corresponds to the requested decimal precision of root_real. System.Max_Digits corresponds to the maximum value for Digits that may be specified in the absence of a real_range_specification, for upward compatibility. These might not be the same if root_real has a base range that does not include ±10.0**(4*Max_Base_Digits).

A floating_point_definition is illegal if the implementation does not support a floating point type that satisfies the requested decimal precision and range.

Implementation defined: What combinations of requested decimal precision and range are supported for floating point types.

Static Semantics

The set of values for a floating point type is the (infinite) set of rational numbers. The machine numbers of a floating point type are the values of the type that can be represented exactly in every unconstrained variable of the type. The base range (see 3.5) of a floating point type is symmetric around zero, except that it can include some extra negative values in some implementations.

Implementation Note: For example, if a 2's complement representation is used for the mantissa rather than a sign-mantissa or 1's complement representation, then there is usually one extra negative machine number.

To be honest: If the Signed_Zeros attribute is True, then minus zero could in a sense be considered a value of the type. However, for most purposes, minus zero behaves the same as plus zero.

The base decimal precision of a floating point type is the number of decimal digits of precision representable in objects of the type. The safe range of a floating point type is that part of its base range for which the accuracy corresponding to the base decimal precision is preserved by all predefined operations.

Implementation Note: In most cases, the safe range and base range are the same. However, for some hardware, values near the boundaries of the base range might result in excessive inaccuracies or spurious overflows when used with certain predefined operations. For such hardware, the safe range would omit such values.

A floating_point_definition defines a floating point type whose base decimal precision is no less than the requested decimal precision. If a real_range_specification is given, the safe range of the floating point type (and hence, also its base range) includes at least the values of the simple expressions given in the real_range_specification. If a real_range_specification is not given, the safe (and base) range of the type includes at least the values of the range \(-10.0**(4*D) \ldots +10.0**(4*D)\) where D is the requested decimal precision. [The safe range might include other values as well. The attributes Safe_First and Safe_Last give the actual bounds of the safe range.]

A floating_point_definition also defines a first subtype of the type. If a real_range_specification is given, then the subtype is constrained to a range whose bounds are given by a conversion of the values of the simple_expressions of the real_range_specification to the type being defined. Otherwise, the subtype is unconstrained.

To be honest: The conversion mentioned above is not an implicit subtype conversion (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type).

There is a predefined, unconstrained, floating point subtype named Float[, declared in the visible part of package Standard].
Dynamic Semantics

[The elaboration of a floating_point_definition creates the floating point type and its first subtype.]

Implementation Requirements

In an implementation that supports floating point types with 6 or more digits of precision, the requested
decimal precision for Float shall be at least 6.

If Long_Float is predefined for an implementation, then its requested decimal precision shall be at least
11.

Implementation Permissions

An implementation is allowed to provide additional predefined floating point types[, declared in the
visible part of Standard], whose (unconstrained) first subtypes have names of the form Short_Float,
Long_Float, Short_Short_Float, Long_Long_Float, etc. Different predefined floating point types are
allowed to have the same base decimal precision. However, the precision of Float should be no greater
than that of Long_Float. Similarly, the precision of Short_Float (if provided) should be no greater than
Float. Corresponding recommendations apply to any other predefined floating point types. There need not
be a named floating point type corresponding to each distinct base decimal precision supported by an
implementation.

Implementation defined: The predefined floating point types declared in Standard.

Implementation Advice

An implementation should support Long_Float in addition to Float if the target machine supports 11 or
more digits of precision. No other named floating point subtypes are recommended for package Standard.
Instead, appropriate named floating point subtypes should be provided in the library package Interfaces
(see B.2).

Implementation Advice: Long_Float should be declared in Standard if the target supports 11 or more digits of
precision. No other named float subtypes should be declared in Standard.

Implementation Note: To promote portability, implementations should explicitly declare the floating point (sub)types
Float and Long_Float in Standard, and leave other predefined float types anonymous. For implementations that already
support Short_Float, etc., upward compatibility argues for keeping such declarations in Standard during the transition
period, but perhaps generating a warning on use. A separate package Interfaces in the predefined environment is
available for pre-declaring types such as Float_32, IEEE_Float_64, etc. See B.2.

NOTES
38 If a floating point subtype is unconstrained, then assignments to variables of the subtype involve only
Overflow_Checks, never Range_Checks.

Examples of floating point types and subtypes:

```ada
type Coefficient is digits 10 range -1.0 .. 1.0;
type Real is digits 8;
type Mass is digits 7 range 0.0 .. 1.0E35;
subtype Probability is Real range 0.0 .. 1.0;   -- a subtype with a smaller range
```

Inconsistencies With Ada 83

No Range_Checks, only Overflow_Checks, are performed on variables (or parameters) of an unconstrained floating
point subtype. This is upward compatible for programs that do not raise Constraint_Error. For those that do raise
Constraint_Error, it is possible that the exception will be raised at a later point, or not at all, if extended range floating
point registers are used to hold the value of the variable (or parameter).

Reason: This change was felt to be justified by the possibility of improved performance on machines with extended-
range floating point registers. An implementation need not take advantage of this relaxation in the range checking; it
can hide completely the use of extended range registers if desired, presumably at some run-time expense.
The syntax rules for floating_point_constraint and floating_accuracy_definition are removed. The syntax rules for floating_point_definition and real_range_specification are new.

A syntax rule for digits_constraint is given in 3.5.9, “Fixed Point Types”. In J.3 we indicate that a digits_constraint may be applied to a floating point subtype_mark as well (to be compatible with Ada 83’s floating_point_constraint).

Discussion of model numbers is postponed to 3.5.8 and G.2. The concept of safe numbers has been replaced by the concept of the safe range of values. The bounds of the safe range are given by T’Safe_First .. T’Safe_Last, rather than - T’Safe_Large .. T’Safe_Large, since on some machines the safe range is not perfectly symmetric. The concept of machine numbers is new, and is relevant to the definition of Succ and Pred for floating point numbers.

### 3.5.8 Operations of Floating Point Types

**Static Semantics**

The following attribute is defined for every floating point subtype S:

\[ S’\text{Digits} \]

S’Digits denotes the requested decimal precision for the subtype S. The value of this attribute is of the type universal_integer. The requested decimal precision of the base subtype of a floating point type T is defined to be the largest value of d for which

\[ \text{ceiling}(d \times \log(10) / \log(T’\text{Machine\_Radix})) + g \leq T’\text{Model\_Mantissa} \]

where g is 0 if Machine_Radix is a positive power of 10 and 1 otherwise.

NOTES

39 The predefined operations of a floating point type include the assignment operation, qualification, the membership tests, and explicit conversion to and from other numeric types. They also include the relational operators and the following predefined arithmetic operators: the binary and unary adding operators – and +, certain multiplying operators, the unary operator abs, and the exponentiation operator.

40 As for all types, objects of a floating point type have Size and Address attributes (see 13.3). Other attributes of floating point types are defined in A.5.3.

**Wording Changes from Ada 95**

\[ \{8652/0004\} \{AI95-00203-01\} \textbf{Corrigendum: Corrected the formula for Digits when the Machine\_Radix is 10.} \]

### 3.5.9 Fixed Point Types

A fixed point type is either an ordinary fixed point type, or a decimal fixed point type. The error bound of a fixed point type is specified as an absolute value, called the *delta* of the fixed point type.

**Syntax**

\[
\text{fixed_point_definition ::= ordinary_fixed_point_definition | decimal_fixed_point_definition}
\]

\[
\text{ordinary_fixed_point_definition ::=}
\delta \text{ static_expression real_range_specification}
\]

\[
\text{decimal_fixed_point_definition ::=}
\delta \text{ static_expression digits static_expression [real_range_specification]}
\]

\[
\text{digits_constraint ::=}
\text{digits static_expression} \text{[range_constraint]}
\]

**Name Resolution Rules**

For a type defined by a fixed_point_definition, the *delta* of the type is specified by the value of the expression given after the reserved word delta; this expression is expected to be of any real type. For a type defined by a decimal_fixed_point_definition (a decimal fixed point type), the number of significant
decimal digits for its first subtype (the *digits* of the first subtype) is specified by the *expression* given after the reserved word *digits*; this *expression* is expected to be of any integer type.

**Legality Rules**

In a *fixed_point_definition* or *digits_constraint*, the *expressions* given after the reserved words *delta* and *digits* shall be static; their values shall be positive.

{AI95-00100-01} The set of values of a fixed point type comprise the integral multiples of a number called the *small* of the type. The *machine numbers of a fixed point type are the values of the type that can be represented exactly in every unconstrained variable of the type*. For a type defined by an *ordinary_fixed_point_definition* (an *ordinary* fixed point type), the *small* may be specified by an *attribute_definition_clause* (see 13.3); if so specified, it shall be no greater than the *delta* of the type. If not specified, the *small* of an ordinary fixed point type is an implementation-defined power of two less than or equal to the *delta*.

**Implementation defined:** The *small* of an ordinary fixed point type.

For a decimal fixed point type, the *small* equals the *delta*; the *delta* shall be a power of 10. If a *real_range_specification* is given, both bounds of the range shall be in the range $-(10^{\text{digits}–1})\ast\text{delta}..+(10^{\text{digits}–1})\ast\text{delta}$.

A *fixed_point_definition* is illegal if the implementation does not support a fixed point type with the given *small* and specified range or *digits*.

**Implementation defined:** What combinations of *small*, range, and *digits* are supported for fixed point types.

For a *subtype_indication* with a *digits_constraint*, the *subtype_mark* shall denote a decimal fixed point subtype.

**To be honest:** Or, as an obsolescent feature, a floating point subtype is permitted — see J.3.

**Static Semantics**

The base range (see 3.5) of a fixed point type is symmetric around zero, except possibly for an extra negative value in some implementations.

An *ordinary_fixed_point_definition* defines an ordinary fixed point type whose base range includes at least all multiples of *small* that are between the bounds specified in the *real_range_specification*. The base range of the type does not necessarily include the specified bounds themselves. An *ordinary_fixed_point_definition* also defines a constrained first subtype of the type, with each bound of its range given by the closer to zero of:

- the value of the conversion to the fixed point type of the corresponding *expression* of the *real_range_specification*;

**To be honest:** The conversion mentioned above is not an *implicit subtype conversion* (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type).

- the corresponding bound of the base range.

A *decimal_fixed_point_definition* defines a decimal fixed point type whose base range includes at least the range $-(10^{\text{digits}–1})\ast\text{delta}..+(10^{\text{digits}–1})\ast\text{delta}$. A *decimal_fixed_point_definition* also defines a constrained first subtype of the type. If a *real_range_specification* is given, the bounds of the first subtype are given by a conversion of the values of the *expressions* of the *real_range_specification*. Otherwise, the range of the first subtype is $-(10^{\text{digits}–1})\ast\text{delta}..+(10^{\text{digits}–1})\ast\text{delta}$.

**To be honest:** The conversion mentioned above is not an *implicit subtype conversion* (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type).
The elaboration of a fixed_point_definition creates the fixed point type and its first subtype.

For a digits_constraint on a decimal fixed point subtype with a given delta, if it does not have a range_constraint, then it specifies an implicit range \(-(10^{**}D-1)*\text{delta} \ldots +(10^{**}D-1)*\text{delta}\), where \(D\) is the value of the expression. A digits_constraint is compatible with a decimal fixed point subtype if the value of the expression is no greater than the digits of the subtype, and if it specifies (explicitly or implicitly) a range that is compatible with the subtype.

Discussion: Except for the requirement that the digits specified be no greater than the digits of the subtype being constrained, a digits_constraint is essentially equivalent to a range_constraint.

Consider the following example:

```ada
type D is delta 0.01 digits 7 range -0.00 .. 9999.99;
```

The compatibility rule implies that the digits_constraint "digits 6" specifies an implicit range of 
\[-9999.99999999 \ldots 9999.99999999\]. Thus, "digits 6" is not compatible with the constraint of \(D\), but "digits 6 range 0.00 .. 9999.9999" is compatible.

\{AI95-00114-01\} A value of a scalar type belongs to a constrained subtype of the type if it belongs to the range of the subtype. Attributes like Digits and Delta have no effect on this fundamental rule. So the obsolescent forms of digits_constraints and delta_constraints that are called “accuracy constraints” in RM83 don’t really represent constraints on the values of the subtype, but rather primarily affect compatibility of the “constraint” with the subtype being “constrained.” In this sense, they might better be called “subtype assertions” rather than “constraints.”

Note that the digits_constraint on a decimal fixed point subtype is a combination of an assertion about the digits of the subtype being further constrained, and a constraint on the range of the subtype being defined, either explicit or implicit.

The elaboration of a digits_constraint consists of the elaboration of the range_constraint, if any. If a range_constraint is given, a check is made that the bounds of the range are both in the range \(-(10^{**}D-1)*\text{delta} \ldots +(10^{**}D-1)*\text{delta}\), where \(D\) is the value of the (static) expression given after the reserved word digits. If this check fails, Constraint_Error is raised.

### Implementation Requirements

The implementation shall support at least 24 bits of precision (including the sign bit) for fixed point types.

Reason: This is sufficient to represent Standard.Duration with a small no more than 50 milliseconds.

### Implementation Permissions

Implementations are permitted to support only smalls that are a power of two. In particular, all decimal fixed point type declarations can be disallowed. Note however that conformance with the Information Systems Annex requires support for decimal smalls, and decimal fixed point type declarations with digits up to at least 18.

Implementation Note: The accuracy requirements for multiplication, division, and conversion (see G.2.1, “Model of Floating Point Arithmetic”) are such that support for arbitrary smalls should be practical without undue implementation effort. Therefore, implementations should support fixed point types with arbitrary values for small (within reason). One reasonable limitation would be to limit support to fixed point types that can be converted to the most precise floating point type without loss of precision (so that Fixed_IO is implementable in terms of Float_IO).

### Notes

41 The base range of an ordinary fixed point type need not include the specified bounds themselves so that the range specification can be given in a natural way, such as:

```ada
type Fraction is delta 2.0**(15) range -1.0 .. 1.0;
```

With 2’s complement hardware, such a type could have a signed 16-bit representation, using 1 bit for the sign and 15 bits for fraction, resulting in a base range of \(-1.0 \ldots 1.0-2.0**(15)\).

### Examples

Examples of fixed point types and subtypes:

```ada
type Volt is delta 0.125 range 0.0 .. 255.0;
```
3.5.9 Fixed Point Types

---

A pure fraction which requires all the available space in a word can be declared as the type Fraction:

```ada
type Fraction is delta System.Fine_Delta range -1.0 .. 1.0;
```

Fraction'Last = 1.0 – System.Fine_Delta

```ada
type Money is delta 0.01 digits 15; -- decimal fixed point
subtype Salary is Money digits 10;
```

Money'Last = 10.0**13 – 0.01, Salary'Last = 10.0**8 – 0.01

### Inconsistencies With Ada 83

In Ada 95, S'Small always equals S'Base'Small, so if an implementation chooses a small for a fixed point type smaller than required by the delta, the value of S'Small in Ada 95 might not be the same as it was in Ada 83.

### Extensions to Ada 83

{AI05-0005-1} Decimal fixed point types are new, though their capabilities are essentially similar to that available in Ada 83 with a fixed point type whose small equals its delta and both are powers of 10. However, in the Information Systems Annex, additional requirements are placed on the support of decimal fixed point types (e.g. a minimum of 18 digits of precision).

### Wording Changes from Ada 83

The syntax rules for fixed_point_constraint and fixed_accuracy_definition are removed. The syntax rule for fixed_point_definition is new. A syntax rule for delta_constraint is included in the Obsolescent features (to be compatible with Ada 83's fixed_point_constraint).

### Wording Changes from Ada 95

{AI95-00100-01} Added wording to define the machine numbers of fixed point types; this is needed by the static evaluation rules.

### 3.5.10 Operations of Fixed Point Types

**Static Semantics**

The following attributes are defined for every fixed point subtype S:

1. S'Small {8652/0005} {AI95-00054-01} S'Small denotes the small of the type of S. The value of this attribute is of the type universal_real. Small may be specified for nonderived ordinary fixed point types via an attribute_definition_clause (see 13.3); the expression of such a clause shall be static.

2.a/3

**Aspect Description for S'Small:** Scale factor for a fixed point type.

3. S'Delta S'Delta denotes the delta of the fixed point subtype S. The value of this attribute is of the type universal_real.

3.a **Reason:** The delta is associated with the subtype as opposed to the type, because of the possibility of an (obsolescent) delta_constraint.

4. S'Fore S'Fore yields the minimum number of characters needed before the decimal point for the decimal representation of any value of the subtype S, assuming that the representation does not include an exponent, but includes a one-character prefix that is either a minus sign or a space. (This minimum number does not include superfluous zeros or underlines, and is at least 2.) The value of this attribute is of the type universal_integer.

5. S'Aft S'Aft yields the number of decimal digits needed after the decimal point to accommodate the delta of the subtype S, unless the delta of the subtype S is greater than 0.1, in which case the attribute yields the value one. [(S'Aft is the smallest positive integer N for which (10**N)*S'Delta is greater than or equal to one.)] The value of this attribute is of the type universal_integer.

The following additional attributes are defined for every decimal fixed point subtype S:
S'Digits  S'Digits denotes the digits of the decimal fixed point subtype S, which corresponds to the number of decimal digits that are representable in objects of the subtype. The value of this attribute is of the type universal_integer. Its value is determined as follows:

- For a first subtype or a subtype defined by a subtype_indication with a digits_constraint, the digits is the value of the expression given after the reserved word digits;
- For a subtype defined by a subtype_indication without a digits_constraint, the digits of the subtype is the same as that of the subtype denoted by the subtype_mark in the subtype_indication.

Implementation Note: Although a decimal subtype can be both range-constrained and digits-constrained, the digits constraint is intended to control the Size attribute of the subtype. For decimal types, Size can be important because input/output of decimal types is so common.

- The digits of a base subtype is the largest integer D such that the range –(10**D–1)*delta .. +(10**D–1)*delta is included in the base range of the type.

S'Scale  S'Scale denotes the scale of the subtype S, defined as the value N such that S'Delta = 10.0**(–N). [The scale indicates the position of the point relative to the rightmost significant digits of values of subtype S.] The value of this attribute is of the type universal_integer.

Ramification: S'Scale is negative if S'Delta is greater than one. By contrast, S'Aft is always positive.

S'Round  S'Round denotes a function with the following specification:

\[
\text{function } S'\text{Round}(X : \text{universal_real}) \text{ return } S'\text{Base}
\]

The function returns the value obtained by rounding X (away from 0, if X is midway between two values of the type of S).

NOTES
42 All subtypes of a fixed point type will have the same value for the Delta attribute, in the absence of delta_constraints (see J.3).  
43 S'Scale is not always the same as S'Aft for a decimal subtype; for example, if S'Delta = 1.0 then S'Aft is 1 while S'Scale is 0.  
44 The predefined operations of a fixed point type include the assignment operation, qualification, the membership tests, and explicit conversion to and from other numeric types. They also include the relational operators and the following predefined arithmetic operators: the binary and unary adding operators – and +, multiplying operators, and the unary operator abs.  
45 As for all types, objects of a fixed point type have Size and Address attributes (see 13.3). Other attributes of fixed point types are defined in A.5.4.

Wording Changes from Ada 95

\{8652/0005\} \{AI95-00054-01\} Corrigendum: Clarified that small may be specified only for ordinary fixed point types.

3.6 Array Types

An array object is a composite object consisting of components which all have the same subtype. The name for a component of an array uses one or more index values belonging to specified discrete types. The value of an array object is a composite value consisting of the values of the components.

Syntax

\[
\text{array_type_definition ::= } \\
\text{unconstrained_array_definition | constrained_array_definition} \\
\text{unconstrained_array_definition ::= } \\
\text{array(index_subtype_definition {, index_subtype_definition}) of component_definition}
\]
3.6 Array Types

**Name Resolution Rules**

For a discrete_subtype_definition that is a range, the range shall resolve to be of some specific discrete type; which discrete type shall be determined without using any context other than the bounds of the range itself (plus the preference for root_integer — see 8.6).

**Legality Rules**

Each index_subtype_definition or discrete_subtype_definition in an array_type_definition defines an index subtype; its type (the index type) shall be discrete.

**Discussion:** An index is a discrete quantity used to select along a given dimension of an array. A component is selected by specifying corresponding values for each of the indices.

The subtype defined by the subtype_indication of a component_definition (the component subtype) shall be a definite subtype.

**Ramification:** This applies to all uses of component_definition, including in record_type_definitions and protected_definitions.

---

This paragraph was deleted. Within the definition of a nonlimited composite type (or a limited composite type that later in its immediate scope becomes nonlimited — see 7.3.1 and 7.5), if a component_definition contains the reserved word aliased and the type of the component is discriminated, then the nominal subtype of the component shall be constrained.

**Reason:** If we allowed the subtype to be unconstrained, then the discriminants might change because of an assignment to the containing (nonlimited) object, thus causing a potential violation of an access subtype constraint of an access value designating the aliased component.

Note that the rule elsewhere defining all aliased discriminated objects to be constrained does not help — that rule prevents assignments to the component itself from doing any harm, but not assignments to the containing object.

We allow this for components within limited types since assignment to the enclosing object is not a problem. Furthermore, it is important to be able to use a default expression for a discriminant in arrays of limited components, since that is the only way to give the components different values for their discriminants. For example:

```
protected type Counter_Type(Initial_Value : Integer := 1) is
    procedure Get_Next(Next_Value : out Integer);  -- Returns the next value on each call, bumping Count before returning.
    private
        Count : Integer := Initial_Value;
    end Counter_Type;
protected body Counter_Type is
    function Next_Id(Counter : access Counter_Type) return Integer is
        Result : Integer;
        begin
            Counter.Get_Next(Result);
            return Result;
        end Next_Id;

C : aliased Counter_Type;
task type T(Who_Am_I : Integer := Next_Id(C'Access)) is
    task body T is
```

---
Task_Array : array (1..100) of aliased T;

— Array of task elements, each with its own unique ID.
— We specify “aliased” so we can use Task_Array(I)'Access.
— This is safe because Task_Array is of a limited type,
— so there is no way an assignment to it could change
— the discriminants of one of its components.

Ramification: Note that this rule applies to array components and record components, but not to protected type
components (since they are always limited).

Static Semantics

An array is characterized by the number of indices (the dimensionality of the array), the type and position
of each index, the lower and upper bounds for each index, and the subtype of the components. The order
of the indices is significant.

A one-dimensional array has a distinct component for each possible index value. A multidimensional
array has a distinct component for each possible sequence of index values that can be formed by selecting
one value for each index position (in the given order). The possible values for a given index are all the
values between the lower and upper bounds, inclusive; this range of values is called the index range. The
bounds of an array are the bounds of its index ranges. The length of a dimension of an array is the number
of values of the index range of the dimension (zero for a null range). The length of a one-dimensional
array is the length of its only dimension.

An array_type_definition defines an array type and its first subtype. For each object of this array type, the
number of indices, the type and position of each index, and the subtype of the components are as in the
type definition; the values of the lower and upper bounds for each index belong to the corresponding
index subtype of its type, except for null arrays (see 3.6.1)].

An unconstrained_array_definition defines an array type with an unconstrained first subtype. Each
index_subtype_definition defines the corresponding index subtype to be the subtype denoted by the
subtype_mark. [ The compound delimiter <> (called a box) of an index_subtype_definition stands for an
undefined range (different objects of the type need not have the same bounds).]

A constrained_array_definition defines an array type with a constrained first subtype. Each discrete-
subtype_definition defines the corresponding index subtype, as well as the corresponding index range for
the constrained first subtype. The constraint of the first subtype consists of the bounds of the index
ranges.

Discussion: {AI05-0005-1} Although there is no nameable unconstrained array subtype in this case, the
predefined slicing and concatenation operations can operate on and yield values that do not necessarily belong to the
first array subtype. This is also true for Ada 83.

The discrete subtype defined by a discrete_subtype_definition is either that defined by the subtype_-indication, or a subtype determined by the range as follows:

- If the type of the range resolves to root_integer, then the discrete_subtype_definition defines a
  subtype of the predefined type Integer with bounds given by a conversion to Integer of the
  bounds of the range;
  
  Reason: This ensures that indexing over the discrete subtype can be performed with regular Integers, rather than only
  universal_integers.
  
  Discussion: We considered doing this by simply creating a “preference” for Integer when resolving the range.
  However, this can introduce Beaujolais effects when the simple_expressions involve calls on functions visible due to
  use clauses.

- Otherwise, the discrete_subtype_definition defines a subtype of the type of the range, with the
  bounds given by the range.
The component_definition of an array_type_definition defines the nominal subtype of the components. If the reserved word aliased appears in the component_definition, then each component of the array is aliased (see 3.10).

Ramification: [AI95-00363-01] In this case, the nominal subtype cannot be an unconstrained discriminated subtype. See 3.8.

Dynamic Semantics

The elaboration of an array_type_definition creates the array type and its first subtype, and consists of the elaboration of any discrete_subtype_definitions and the component_definition.

Dynamic Semantics

The elaboration of a discrete_subtype_definition that does not contain any per-object expressions creates the discrete subtype, and consists of the elaboration of the subtype_indication or the evaluation of the range. The elaboration of a discrete_subtype_definition that contains one or more per-object expressions is defined in 3.8. The elaboration of a component_-definition in an array_type_definition consists of the elaboration of the subtype_indication or access_definition. The elaboration of any discrete_subtype_definitions and the elaboration of the component_definition are performed in an arbitrary order.

Static Semantics

For an array_type with a scalar component type, the following language-defined representation aspect may be specified with an aspect_specification (see 13.1.1):

Default_Component_Value

This aspect shall be specified by a static expression, and that expression shall be explicit, even if the aspect has a boolean type. Default_Component_Value shall be specified only on a full_type_declaration.

Reason: The part about requiring an explicit expression is to disallow omitting the value for this aspect, which would otherwise be allowed by the rules of 13.1.1.

This is a representation attribute in order to disallow specifying it on a derived type that has inherited primitive subprograms; that is necessary as the sizes of out parameters could be different whether or not a Default_Value is specified (see 6.4.1).

Aspect Description for Default_Component_Value: Default value for the components of an array-of-scalar subtype.

Name Resolution Rules

The expected type for the expression specified for the Default_Component_Value aspect is the component type of the array type defined by the full_type_declaration on which it appears.

Examples

Examples of type declarations with unconstrained array definitions:

```
type Vector is array(Integer range <>) of Real;
type Matrix is array(Integer range <>, Integer range <>) of Real;
type Bit_Vector is array(Integer range <>, Integer range <> >) of Boolean;
type Roman is array(Positive range <> >) of Roman_Digit; -- see 3.5.2
```
Examples of type declarations with constrained array definitions:

```ada
    type Table is array(1 .. 10) of Integer;
    type Schedule is array(Day) of Boolean;
    type Line is array(1 .. Max_Line_Size) of Character;
```

Examples of object declarations with array type definitions:

```ada
{AI95-00433-01} Grid : array(1 .. 80, 1 .. 100) of Boolean;
Mix : array(Color range Red .. Green) of Boolean;
Msg_Table : constant array(Error_Code) of access constant String :=
               (Too_Big => new String("Result too big"), Too_Small => ...
Page : array(Positive range <>) of Line := -- an array of arrays
               (1 | 50 => Line'(1 | Line'Last => '+', others => '-'),
               2 .. 49 => Line'(1 | Line'Last => '|', others => ' '));
-- Page is constrained by its initial value to (1..50)
```

Extensions to Ada 83

The syntax rule for component_definition is modified to allow the reserved word aliased.

The syntax rules for unconstrained_array_definition and constrained_array_definition are modified to use component_definition (instead of component_subtype_indication). The effect of this change is to allow the reserved word aliased before the component_subtype_indication.

A range in a discrete_subtype_definition may use arbitrary universal expressions for each bound (e.g. –1 .. 3+5), rather than strictly "implicitly convertible" operands. The subtype defined will still be a subtype of Integer.

Wording Changes from Ada 83

We introduce a new syntactic category, discrete_subtype_definition, as distinct from discrete_range. These two constructs have the same syntax, but their semantics are quite different (one defines a subtype, with a preference for Integer subtypes, while the other just selects a subrange of an existing subtype). We use this new syntactic category in for loops and entry families.

The syntax for index_constraint and discrete_range have been moved to their own subclause, since they are no longer used here.

The syntax rule for component_definition (formerly component_subtype_definition) is moved here from RM83-3.7.

Extensions to Ada 95

{AI95-00230-01} {AI95-00406-01} Array components can have an anonymous access type.

{AI95-00363-01} The prohibition against unconstrained discriminated aliased components has been lifted. It has been replaced by a prohibition against the actual troublemakers: general access discriminant constraints (see 3.7.1).

Wording Changes from Ada 95

{8652/0002} {AI95-00171-01} Corrigendum: Added wording to allow the elaboration of per-object constraints for constrained arrays.

Extensions to Ada 2005

{AI05-0228-1} The new aspect Default_Component_Value allows defining implicit initial values (see 3.3.1) for arrays of scalar types.

3.6.1 Index Constraints and Discrete Ranges

An index_constraint determines the range of possible values for every index of an array subtype, and thereby the corresponding array bounds.

Syntax

```
    index_constraint ::= (discrete_range | discrete_range)
    discrete_range ::= discrete_subtype_indication | range
```
Name Resolution Rules

The type of a `discrete_range` is the type of the subtype defined by the `subtype_indication`, or the type of the range. For an `index_constraint`, each `discrete_range` shall resolve to be of the type of the corresponding index.

**Discussion:** In Ada 95, `index_constraints` only appear in a `subtype_indication`; they no longer appear in `constrained_array_definitions`.

Legality Rules

An `index_constraint` shall appear only in a `subtype_indication` whose `subtype_mark` denotes either an unconstrained array subtype, or an unconstrained access subtype whose designated subtype is an unconstrained array subtype; in either case, the `index_constraint` shall provide a `discrete_range` for each index of the array type.

Static Semantics

A `discrete_range` defines a range whose bounds are given by the `range`, or by the range of the subtype defined by the `subtype_indication`.

Dynamic Semantics

An `index_constraint` is `compatible` with an unconstrained array subtype if and only if the index range defined by each `discrete_range` is compatible (see 3.5) with the corresponding index subtype. If any of the `discrete_ranges` defines a null range, any array thus constrained is a `null array`, having no components. An array value `satisfies` an `index_constraint` if at each index position the array value and the `index_constraint` have the same index bounds.

**Ramification:** There is no need to define compatibility with a constrained array subtype, because one is not allowed to constrain it again.

The elaboration of an `index_constraint` consists of the evaluation of the `discrete_range`(s), in an arbitrary order. The evaluation of a `discrete_range` consists of the elaboration of the `subtype_indication` or the evaluation of the `range`.

**Examples of array declarations including an index constraint:**

``` ada
Board   : Matrix(1 .. 8, 1 .. 8);  -- see 3.6
Rectangle : Matrix(1 .. 20, 1 .. 30);
Inverse  : Matrix(1 .. N, 1 .. N);  -- N need not be static
Filter   : Bit_Vector(0 .. 31);
```

**Example of array declaration with a constrained array subtype:**

``` ada
My_Schedule : Schedule;  -- all arrays of type Schedule have the same bounds
```

**Example of record type with a component that is an array:**

``` ada
type Var_Line(Length : Natural) is
record
   Image : String(1 .. Length);
end record;
```
Null_Line : Var_Line(0);  -- Null_Line.Image is a null array

Extensions to Ada 83

We allow the declaration of a variable with a nominally unconstrained array subtype, so long as it has an initialization expression to determine its bounds.

Wording Changes from Ada 83

We have moved the syntax for index_constraint and discrete_range here since they are no longer used in constrained_array_definitions. We therefore also no longer have to describe the (special) semantics of index_constraints and discrete_ranges that appear in constrained_array_definitions.

The rules given in RM83-3.6.1(5,7-10), which define the bounds of an array object, are redundant with rules given elsewhere, and so are not repeated here. RM83-3.6.1(6), which requires that the (nominal) subtype of an array variable be constrained, no longer applies, so long as the variable is explicitly initialized.

3.6.2 Operations of Array Types

Legality Rules

[The argument N used in the attribute_designators for the N-th dimension of an array shall be a static expression of some integer type.] The value of N shall be positive (nonzero) and no greater than the dimensionality of the array.

Static Semantics

{8652/0006} {AI95-00030-01} The following attributes are defined for a prefix A that is of an array type [(after any implicit dereference)], or denotes a constrained array subtype:

Ramification: These attributes are not defined if A is a subtype-mark for an access-to-array subtype. They are defined (by implicit dereference) for access-to-array values.

A'First A'First denotes the lower bound of the first index range; its type is the corresponding index type.

A'First(N) A'First(N) denotes the lower bound of the N-th index range; its type is the corresponding index type.

A'Last A'Last denotes the upper bound of the first index range; its type is the corresponding index type.

A'Last(N) A'Last(N) denotes the upper bound of the N-th index range; its type is the corresponding index type.

A'Range A'Range is equivalent to the range A'First .. A'Last, except that the prefix A is only evaluated once.

A'Range(N) A'Range(N) is equivalent to the range A'First(N) .. A'Last(N), except that the prefix A is only evaluated once.

A'Length A'Length denotes the number of values of the first index range (zero for a null range); its type is universal_integer.

A'Length(N) A'Length(N) denotes the number of values of the N-th index range (zero for a null range); its type is universal_integer.

Implementation Advice

{AI05-0229-1} An implementation should normally represent multidimensional arrays in row-major order, consistent with the notation used for multidimensional array aggregates (see 4.3.3). However, if
convention a pragma Convention(Fortran is specified for,...) applies to a multidimensional array type, then column-major order should be used instead (see B.5, “Interfacing with Fortran”).

Implementation Advice: Multidimensional arrays should be represented in row-major order, unless the array has convention Fortran.

NOTES
50 The attribute references A'First and A'First(1) denote the same value. A similar relation exists for the attribute references A'Last, A'Range, and A'Length. The following relation is satisfied (except for a null array) by the above attributes if the index type is an integer type:

\[ A'Length(N) = A'Last(N) - A'First(N) + 1 \]

51 An array type is limited if its component type is limited (see 7.5).

52 The predefined operations of an array type include the membership tests, qualification, and explicit conversion. If the array type is not limited, they also include assignment and the predefined equality operators. For a one-dimensional array type, they include the predefined concatenation operators (if nonlimited) and, if the component type is discrete, the predefined relational operators; if the component type is boolean, the predefined logical operators are also included.

53 [AI95-00287-01] A component of an array can be named with an indexed_component. A value of an array type can be specified with an array_aggregate, unless the array type is limited. For a one-dimensional array type, a slice of the array can be named; also, string literals are defined if the component type is a character type.

Examples

Examples (using arrays declared in the examples of subclause 3.6.1):

```
--  Filter'First = 0    Filter'Last = 31    Filter'Length = 32
--  Rectangle'Last(1) = 20  Rectangle'Last(2) = 30
```

3.6.3 String Types

Static Semantics

A one-dimensional array type whose component type is a character type is called a string type.

\[ \{AI95-00285-01\} \] There are three predefined string types, String, and Wide_String, and Wide_Wide_String, each indexed by values of the predefined subtype Positive; these are declared in the visible part of package Standard:

```
subtype Positive is Integer range 1 .. Integer'Last;
{AI95-00285-01} type String is array(Positive range <>) of Character;
type Wide_String is array(Positive range <>) of Wide_Character;
type Wide_Wide_String is array(Positive range <>) of Wide_Wide_Character;
```

NOTES
54 String literals (see 2.6 and 4.2) are defined for all string types. The concatenation operator & is predefined for string types, as for all nonlimited one-dimensional array types. The ordering operators <, <=, >, and >= are predefined for string types, as for all one-dimensional discrete array types; these ordering operators correspond to lexicographic order (see 4.5.2).

Examples

Examples of string objects:

```
Stars     : String(1 .. 120) := (1 .. 120 => '*');
Question  : constant String := "How many characters?";
    -- Question'First = 1, Question'Last = 20
    -- Question'Length = 20 (the number of characters)
Ask_Twice : String := Question & Question;  -- constrained to (1..40)
Ninety_Six : constant Roman := "XCVI";   -- see 3.5.2 and 3.6
```

Inconsistencies With Ada 83

The declaration of Wide_String in Standard hides a use-visible declaration with the same defining_identifier. In rare cases, this might result in an inconsistency between Ada 83 and Ada 95.
Incompatibilities With Ada 83

Because both String and Wide_String are always directly visible, an expression like

```
"a" < "b c"
```

is now ambiguous, whereas in Ada 83 both string literals could be resolved to type String.

Extensions to Ada 83

The type Wide_String is new (though it was approved by ARG for Ada 83 compilers as well).

Wording Changes from Ada 83

We define the term string type as a natural analogy to the term character type.

Inconsistencies With Ada 95

{AI95-00285-01} The declaration of Wide_Wide_String in Standard hides a use-visible declaration with the same defining_identifier. In the (very) unlikely event that an Ada 95 program had depended on such a use-visible declaration, and the program remains legal after the substitution of Standard.Wide_Wide_String, the meaning of the program will be different.

Extensions to Ada 95

{AI95-00285-01} The type Wide_Wide_String is new.

3.7 Discriminants

{AI95-00251-01} {AI95-00326-01} A composite type (other than an array or interface type) can have discriminants, which parameterize the type. A known_discriminant_part specifies the discriminants of a composite type. A discriminant of an object is a component of the object, and is either of a discrete type or an access type. An unknown_discriminant_part in the declaration of a partial view of a type specifies that the discriminants of the type are unknown for the given view; all subtypes of such a partial view are indefinite subtypes.]

Glossary entry: A discriminant is a parameter for of a composite type. It can control, for example, the bounds of a component of the type if the component is of a discrete type. A discriminant for of a task type can be used to pass data to a task of the type upon creation.

Discussion: {AI95-00114-01} A view of a type, and all of its subtypes of the view, have unknown discriminants when the number or names of the discriminants, if any, are unknown at the point of the type declaration for the view. A discriminant_part of (<>) is used to indicate unknown discriminants.

Language Design Principles

{AI95-00402-01} When an access discriminant is initialized at the time of object creation with an allocator of an anonymous type, the allocated object and the object with the discriminant are tied together for their lifetime. They should be allocated out of the same storage pool, and then at the end of the lifetime of the enclosing object, finalized and reclaimed together. In this case, the allocated object is called a coextension (see 3.10.2).

Discussion: The above principle when applied to a nonlimited type implies that such an object may be copied only to a shorter-lived object, because attempting to assign it to a longer-lived object would fail because the access discriminants would not match. In a copy, the lifetime connection between the enclosing object and the allocated object does not exist. The allocated object is tied in the above sense only to the original object. Other copies have only secondary references to it.

Note that when an allocator appears as a constraint on an access discriminant in a subtype indication that is elaborated independently from object creation, no such connection exists. For example, if a named constrained subtype is declared via "subtype Constr is Rec(Acc_Discrim => new T);" or if such an allocator appears in the subtype indication for a component, the allocator is evaluated when the subtype indication is elaborated, and hence its lifetime is typically longer than the objects or components that will later be subject to the constraint. In these cases, the allocated object should not be reclaimed until the subtype indication goes out of scope.

Syntax

discriminant_part ::= unknown_discriminant_part | known_discriminant_part
unknown_discriminant_part ::= (<>)

known_discriminant_part ::= (discriminant_specification ; discriminant_specification)

\{AI95-00231-01\} discriminant_specification ::= defining_identifier_list : [null_exclusion] subtype_mark [= default_expression]
| defining_identifier_list : access_definition [= default_expression]

default_expression ::= expression

Name Resolution Rules

The expected type for the default_expression of a discriminant_specification is that of the corresponding discriminant.

Legality Rules

\{8652/0007\} \{AI95-00098-01\} \{AI95-00251-01\} A discriminant_part known_discriminant_part is only permitted in a declaration for a composite type that is not an array or interface type ([this includes generic formal types]. A type declared with a known_discriminant_part is called a discriminated type, as is a type that inherits (known) discriminants.

Implementation Note: Discriminants on array types were considered, but were omitted to ease (existing) implementations.

Discussion: Note that the above definition for “discriminated type” does not include types declared with an unknown_discriminant_part. This seems consistent with Ada 83, where such types (in a generic formal part) would not be considered discriminated types. Furthermore, the full type for a type with unknown discriminants need not even be composite, much less have any discriminants.

8.1/1

\{8652/0007\} \{AI95-00098-01\} On the other hand, unknown_discriminant_parts cannot be applied to type declarations that cannot have a known_discriminant_part. There is no point in having unknown discriminants on a type that can never have discriminants (for instance, a formal modular type), even when these are allowed syntactically.

9/2

\{AI95-00231-01\} \{AI95-00254-01\} The subtype of a discriminant may be defined by an optional null_exclusion and a subtype_mark, in which case the subtype_mark shall denote a discrete or access subtype, or it may be defined by an access_definition [(in which case the subtype_mark of the access_definition may denote any kind of subtype)]. A discriminant that is defined by an access_definition is called an access discriminant and is of an anonymous access general access_variable type whose designated subtype is denoted by the subtype_mark of the access_definition.

9.a/2

This paragraph was deleted.

Reason: [AI95-00230-01] In an early version of Ada 9X, we allowed access discriminants on nonlimited types, but this created unpleasant complexities. It turned out to be simpler and more uniform to allow discriminants of a named access type on any discriminated type, and keep access discriminants just for limited types.

9.b

Note that discriminants of a named access type are not considered “access discriminants.” Similarly, “access parameter” only refers to a formal parameter defined by an access_definition.

9.1/3

\{AI95-00402-01\} \{AI05-0214-1\} Default expressions shall be provided either for all or for none of the discriminants of a known discriminant_part. No default expressions are permitted in a known_discriminant_part in a declaration of a nonlimited tagged type or a generic formal type.

Reason: The all-or-none rule is related to the rule that a discriminant constraint shall specify values for all discriminants. One could imagine a different rule that allowed a constraint to specify only some of the discriminants, with the others provided by default. Having defaults for discriminants has a special significance — it allows objects of the type to be unconstrained, with the discriminants alterable as part of assigning to the object.

9.c/2

\{AI05-0214-1\} Defaults for discriminants of tagged types are disallowed so that every object of a nonlimited tagged type is constrained, either by an explicit constraint, or by its initial discriminant values. This substantially simplifies the semantic rules and the implementation of inherited dispatching operations. We don't need this rule for limited tagged types, as the discriminants of such objects cannot be changed after the object is created in any case — no full-object assignment is supported, and that is required to change discriminant values. For generic formal types, the restriction simplifies the type matching rules. If one simply wants a "default" value for the discriminants, a constrained subtype can be declared for future use.
A discriminant specification for an access discriminant may have a default expression shall appear only in the declaration for an immutably limited type (see 7.5), a task or protected type, or for a type that is a descendant of an explicitly limited record type with the reserved word limited in its (full) definition or in that of one of its ancestors.

In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Discussion: This rule implies that a type can have a default for an access discriminant if the type is limited, but not if the only reason it's limited is because of a limited component. Compare with the definition of limited type and immutably limited type in 7.5. Also, recall that a "descendant" includes the type itself; so an explicitly limited record type can have defaults.

Ramification: It is a consequence of this rule that only a return-by-reference type can have an access discriminant (see 6.5). This is important to avoid dangling references to local variables. A (nonformal) limited private type can always have a default for an access discriminant, because having the default itself makes the type immutably limited. Such a private type must necessarily have a full type with the same access discriminant with a default, and thus the full type will always be immutably limited (if legal).

Reason: We also considered the following rules for access discriminants:

- If a type has an access discriminant, this automatically makes it limited, just like having a limited component automatically makes a type limited. This was rejected because it decreases program readability, and because it seemed error prone (two bugs in a previous version of the RM9X were attributable to this rule).

- A type with an access discriminant shall be limited. This is equivalent to the rule we actually chose for Ada 95, except that it allows a type to have an access discriminant if it is limited just because of a limited component. For example, any record containing a task would be allowed to have an access discriminant, whereas the actual rule requires "limited record". This rule was also rejected due to readability concerns, and because would interact badly with the rules for limited types that "become nonlimited".

- A type may have an access discriminant if it is an immutably limited limited partial view, or a task, protected, or explicitly limited record type. This was the rule chosen for Ada 95.

- Any type may have an access discriminant. For nonlimited type, there is no special accessibility for access discriminants; they're the same as any other anonymous access component. For a limited type, they have the special accessibility of Ada 95. However, this doesn't work because a limited partial view can have a nonlimited full view -- giving the two views different accessibility.

- Any type may have an access discriminant, as above. However, special accessibility rules only apply to types that are immutably limited (task, protected, and explicitly limited records). However, this breaks privacy; worse, Legality Rules depend on the definition of accessibility.

- Any type may have an access discriminant, as above. Limited types have special accessibility, while nonlimited types have normal accessibility. However, a limited partial view with an access discriminant can only be completed by an immutably limited task, protected, or explicitly limited record type. That prevents accessibility from changing. A runtime accessibility check is required on generic formal types with access discriminants. However, changing between limited and nonlimited types would have far-reaching consequences for access discriminants — which is uncomfortable.

- Any type may have an access discriminant. All types have special accessibility. This was considered early during the Ada 9X process, but was dropped for "unpleasant complexities", which unfortunately aren't recorded. It does seem that an accessibility check would be needed on assignment of such a type, to avoid copying an object with a discriminant pointing to a local object into a more global object (and thus creating a dangling pointer).

- Any type may have an access discriminant, but access discriminants cannot have defaults. All types have special accessibility. This gets rid of the problems on assignment (you couldn't change such a discriminant), but it would be horribly incompatible with Ada 95.

- Any type may have an access discriminant, but access discriminants may have defaults only if they are of an immutably limited limited type. This is the rule chosen for Ada 2005, as it is not incompatible, and it doesn't require weird accessibility checks.

This paragraph was deleted. Default expressions shall be provided either for all or for none of the discriminants of a known_discriminant_part. No default expressions are permitted in a known_discriminant_part in a declaration of a tagged type [or a generic formal type].

Reason: The all-or-none rule is related to the rule that a discriminant constraint shall specify values for all discriminants. One could imagine a different rule that allowed a constraint to specify only some of the discriminants, with the others provided by default. Having defaults for discriminants has a special significance — it allows objects of the type to be unconstrained, with the discriminants alterable as part of assigning to the object.
Defaults for discriminants of tagged types are disallowed so that every object of a tagged type is constrained, either by an explicit constraint, or by its initial discriminant values. This substantially simplifies the semantic rules and the implementation of inherited dispatching operations. For generic formal types, the restriction simplifies the type matching rules. If one simply wants a “default” value for the discriminants, a constrained subtype can be declared for future use.

For a type defined by a derived_type_definition, if a known_discriminant_part is provided in its declaration, then:

- The parent subtype shall be constrained;
- If the parent type is not a tagged type, then each discriminant of the derived type shall be used in the constraint defining the parent subtype;
- If a discriminant is used in the constraint defining the parent subtype, the subtype of the discriminant shall be statically compatible (see 4.9.1) with the subtype of the corresponding parent discriminant.

**Reason:** This ensures that on conversion (or extension via an extension aggregate) to a distantly related type, if the discriminants satisfy the target type's requirements they satisfy all the intermediate types' requirements as well.

**Ramification:** There is no requirement that the new discriminant have the same (or any) default_expression as the parent's discriminant.

A **discriminant_specification** declares a discriminant; the **subtype_mark** denotes its subtype unless it is an access discriminant, in which case the discriminant's subtype is the anonymous access-to-variable subtype defined by the access_definition.

[For a type defined by a derived_type_definition, each discriminant of the parent type is either inherited, constrained to equal some new discriminant of the derived type, or constrained to the value of an expression.] When inherited or constrained to equal some new discriminant, the parent discriminant and the discriminant of the derived type are said to correspond. Two discriminants also correspond if there is some common discriminant to which they both correspond. A discriminant corresponds to itself as well. If a discriminant of a parent type is constrained to a specific value by a derived_type_definition, then that discriminant is said to be specified by that derived_type_definition.

**Ramification:** The correspondence relationship is transitive, symmetric, and reflexive. That is, if A corresponds to B, and B corresponds to C, then A, B, and C each corresponds to A, B, and C in all combinations.

A constraint that appears within the definition of a discriminated type depends on a discriminant of the type if it names the discriminant as a bound or discriminant value. A **component_definition** depends on a discriminant if its constraint depends on the discriminant, or on a discriminant that corresponds to it.

**Ramification:** A constraint in a task_body is not considered to depend on a discriminant of the task type, even if it names it. It is only the constraints in the type definition itself that are considered dependents. Similarly for protected types.

A component depends on a discriminant if:

- Its component_definition depends on the discriminant; or
- It is declared in a variant_part that is governed by the discriminant; or
• It is a component inherited as part of a derived_type_definition, and the constraint of the parent_subtype_indication depends on the discriminant; or

Reason: When the parent subtype depends on a discriminant, the parent part of the derived type is treated like a discriminant-dependent component.

Ramification: Because of this rule, we don't really need to worry about “corresponding” discriminants, since all the inherited components will be discriminant-dependent if there is a new known_discriminant_part whose discriminants are used to constrain the old discriminants.

• It is a subcomponent of a component that depends on the discriminant.

Reason: The concept of discriminant-dependent (sub)components is primarily used in various rules that disallow renaming or ‘Access, or specify that certain discriminant-changing assignments are erroneous. The goal is to allow implementations to move around or change the size of discriminant-dependent subcomponents upon a discriminant-changing assignment to an enclosing object. The above definition specifies that all subcomponents of a discriminant-dependent component or parent part are themselves discriminant-dependent, even though their presence or size does not in fact depend on a discriminant. This is because it is likely that they will move in a discriminant-changing assignment if they are a component of one of several discriminant-dependent parts of the same record.

Each value of a discriminated type includes a value for each component of the type that does not depend on a discriminant; [this includes the discriminants themselves]. The values of discriminants determine which other component values are present in the value of the discriminated type.

To be honest: Which values are present might depend on discriminants of some ancestor type that are constrained in an intervening derived_type_definition. That’s why we say “values of discriminants” instead of “values of the discriminants” — a subtle point.

A type declared with a known_discriminant_part is said to have known discriminants; its first subtype is unconstrained. A type declared with an unknown_discriminant_part is said to have unknown discriminants. A type declared without a discriminant_part has no discriminants, unless it is a derived type; if derived, such a type has the same sort of discriminants (known, unknown, or none) as its parent (or ancestor) type. A tagged class-wide type also has unknown discriminants. [Any subtype of a type with unknown discriminants is an unconstrained and indefinite subtype (see 3.2 and 3.3).]

Discussion: {AI95-00114-01} An unknown_discriminant_part “(<>)” is only permitted in the declaration of a (generic or nongeneric) private type, private extension, incomplete_type, or formal derived type. Hence, only such types, descendants thereof, and class-wide types can have unknown discriminants. An unknown_discriminant_part is used to indicate that the corresponding actual or full type might have discriminants without defaults, or be an unconstrained array subtype. Tagged class-wide types are also considered to have unknown discriminants because discriminants can be added by type extensions, so the total number of discriminants of any given value of a tagged class-wide type is not known at compile time.

{AI95-00287-01} A subtype with unknown discriminants is indefinite, and hence an object of such a subtype needs explicit initialization. If the subtype is limited, no (stand alone) objects can be declared since initialization is not permitted (though formal parameters are permitted, and objects of the actual/full type will generally be declarable). A limited private type with unknown discriminants is “extremely” limited; objects of such a type can be initialized only by subprograms (either procedures with a parameter of the type, or a function returning the type) declared in the package. Subprograms declared elsewhere can operate on and even return the type, but they can only initialize the object by calling (ultimately) a subprogram in the package declaring the type. Such a type is useful for keeping complete control over object creation within the package declaring the type.

A partial view of a type might have unknown discriminants, while the full view of the same type might have known, unknown, or no discriminants.

Dynamic Semantics

{AI95-00230-01} {AI95-00416-01} For an access discriminant, its access_definition is elaborated when the value of the corresponding access discriminant is defined: either by evaluation of its default_expression, or by elaboration of a discriminant_constraint, or by an assignment that initializes the enclosing object. [The elaboration of an access_definition creates the anonymous access type. When the expression defining the access discriminant is evaluated, it is converted to this anonymous access type (see 4.6).]
Ramification: \{AI95-00231-01\} \{AI95-00416-01\} The conversion of the expression defining the access discriminant to the anonymous access type raises Program_Error Constraint_Error if the initial value is null, or, for an object created by an allocator of an access type T, if the initial value is an access parameter that designates a view whose accessibility level is deeper than that of T.

NOTES
55 If a discriminated type has default_expressions for its discriminants, then unconstrained variables of the type are permitted, and the values of the discriminants can be changed by an assignment to such a variable. If defaults are not provided for the discriminants, then all variables of the type are constrained, either by explicit constraint or by their initial value; the values of the discriminants of such a variable cannot be changed after initialization.

Discussion: This connection between discriminant defaults and unconstrained variables can be a source of confusion. For Ada 95, we considered various ways to break the connection between defaults and unconstrainedness, but ultimately gave up for lack of a sufficiently simple and intuitive alternative.

An unconstrained subtype with defaults is called a mutable subtype, and a variable of such a subtype is called a mutable variable, because the discriminants of such a variable can change. There are no mutable arrays (that is, the bounds of an array object can never change), because there is no way in the language to define default values for the bounds. Similarly, there are no mutable class-wide subtypes, because there is no way to define the default tag, and defaults for discriminants are not allowed in the tagged case. Mutable tags would also require a way for the maximum possible size of such a class-wide subtype to be known. (In some implementations, all mutable variables are allocated with the maximum possible size. This approach is appropriate for real-time applications where implicit use of the heap is inappropriate.)

56 The default_expression for a discriminant of a type is evaluated when an object of an unconstrained subtype of the type is created.

57 Assignment to a discriminant of an object (after its initialization) is not allowed, since the name of a discriminant is a constant; neither assignment_statements nor assignments inherent in passing as an in_out or out parameter are allowed. Note however that the value of a discriminant can be changed by assigning to the enclosing object, presuming it is an unconstrained variable.

Discussion: \{AI95-00114-01\} An unknown_discriminant_part is permitted only in the declaration of a private type (including generic formal private), private extension, incomplete_type, or generic formal derived type. These are the things that will have a corresponding completion or generic actual, which will either define the discriminants, or say there are none. The (<>) indicates that the actual/full subtype might be an indefinite subtype. An unknown_discriminant_part is not permitted in a normal untagged derived type declaration, because there is no separate full type declaration for such a type. Note that (<>) allows unconstrained array bounds; those are somewhat like undefaulted discriminants.

For a derived type, either the discriminants are inherited as is, or completely respecified in a new discriminant_part. In this latter case, each discriminant of the parent type shall be constrained, either to a specific value, or to equal one of the new discriminants. Constraining a parent type's discriminant to equal one of the new discriminants is like a renaming of the discriminant, except that the subtype of the new discriminant can be more restrictive than that of the parent's one. In any case, the new discriminant can share storage with the parent's discriminant.

58 A discriminant that is of a named access type is not called an access discriminant; that term is used only for discriminants defined by an access_definition.

Examples of discriminated types:

```ada
32 Examples of discriminated types:
33 type Buffer(Size : Buffer_Size := 100) is -- see 3.5.4
   record
      Pos   : Buffer_Size := 0;
      Value : String(1 .. Size);
   end record;
34 type Matrix_Rec(Rows, Columns : Integer) is
   record
      Mat : Matrix(1 .. Rows, 1 .. Columns); -- see 3.6
   end record;
35 type Square(Side : Integer) is new Matrix_Rec(Rows => Side, Columns => Side);
36 type Double_Square(Number : Integer) is
   record
      Left  : Square(Number);
      Right : Square(Number);
   end record;
```

27.a/2
task type Worker(Prio : System.Priority; Buf : access Buffer) with Priority => Prio is -- see D.1
pragma Priority(Prio); -- see D.1
entry Fill;
entry Drain;
end Worker;

---

type Item(Number : Positive) is record
  Content : Integer;
-- no component depends on the discriminant
end record.

Extensions to Ada 83

The syntax for a discriminant_specification is modified to allow an access discriminant, with a type specified by an access_definition (see 3.10).

Discriminants are allowed on all composite types other than array and interface types.

Discriminants may be of an access type.

Wording Changes from Ada 83

Discriminant_parts are not elaborated, though an access_definition is elaborated when the discriminant is initialized.

Extensions to Ada 95

Access discriminants (anonymous access types used as a discriminant) can be used on any type allowing discriminants. Defaults aren't allowed on discriminants of nonlimited types, however, so that accessibility problems don't happen on assignment.

null_exclusion can be used in the declaration of a discriminant.

Wording Changes from Ada 95

Corrigendum: The wording was clarified so that types that cannot have discriminants cannot have an unknown_discriminant_part.

Added wording to prevent interfaces from having discriminants. We don't want interfaces to have any components.

Removed wording which implied or required an access discriminant to have an access-to-object type (anonymous access types can now be access-to-subprogram types as well).

Fixed the wording of the introduction to this subclause to reflect that both incomplete and partial views can have unknown discriminants. That was always true, but for some reason this wording specified partial views.

Changed the wording to use the new term "explicitly limited record", which makes the intent much clearer (and eliminates confusion with derived types that happen to contain the reserved word limited).

Incompatibilities With Ada 2005

Correction: Changed the rules for when access discriminants can have defaults to depend on the new definition for immutably limited types; this will help ensure that unusual corner cases are properly handled. Note that the Ada 2005 rule was unintentionally incompatible with the Ada 95 rule (as enforced by the ACATS); this change brings it back into alignment with actual practice. So there should be no practical incompatibility.

Extensions to Ada 2005

A limited tagged type may now have defaults for its discriminants.

Wording Changes from Ada 2005

Correction: Moved implicit conversion Legality Rule to 8.6.

3.7.1 Discriminant Constraints

A discriminant_constraint specifies the values of the discriminants for a given discriminated type.
Language Design Principles

The rules in this subclause are intentionally parallel to those given in 4.3.1, “Record Aggregates”.

Syntax

```
3.7.1 Discriminant Constraints
```

```
4
A discriminant_association is said to be named if it has one or more discriminant_selector_names; it is otherwise said to be positional. In a discriminant_constraint, any positional associations shall precede any named associations.
```

Name Resolution Rules

Each selector_name of a named discriminant_association shall resolve to denote a discriminant of the subtype being constrained; the discriminants so named are the associated discriminants of the named association. For a positional association, the associated discriminant is the one whose discriminant_specification occurred in the corresponding position in the known_discriminant_part that defined the discriminants of the subtype being constrained.

The expected type for the expression in a discriminant_association is that of the associated discriminant(s).

Legality Rules

A discriminant_constraint is only allowed in a subtype_indication whose subtype_mark denotes either an unconstrained discriminated subtype, or an unconstrained access subtype whose designated subtype is an unconstrained discriminated subtype. However, in the case of a general access subtype, a discriminant_constraint is legal only if any dereference of a value of the access type is known to be constrained (see 3.3). A discriminant_constraint is illegal if the designated type has a partial view that is constrained or, for a general access subtype, has default_expressions for its discriminants.

Reason:

The second rule is necessary to prevent assignments that change the discriminant of a constrained object. See the defect report for examples.

Discussion:

The second rule will only use the indefinite or dereference bullets in the definition of “known to be constrained”. The rule is worded in terms of “known to be constrained” in order to capture the special rules that apply in generic bodies (rather than repeating them and getting them subtly wrong).

A named discriminant_association with more than one selector_name is allowed only if the named discriminants are all of the same type. A discriminant_constraint shall provide exactly one value for each discriminant of the subtype being constrained.
The expression associated with an access discriminant shall be of a type convertible to the anonymous access type.

**Ramification:** In addition, 8.6 requires that the expression associated with an access discriminant is convertible (see 4.6) to the anonymous access type. This implies both convertibility of designated types, and static accessibility. This implies that if an object of type T with an access discriminant is created by an allocator for an access type A, then it requires that the type of the expression associated with the access discriminant have an accessibility level that is not statically deeper than that of A. This is to avoid dangling references.

**Dynamic Semantics**

A discriminant constraint is compatible with an unconstrained discriminated subtype if each discriminant value belongs to the subtype of the corresponding discriminant.

**Ramification:** The "dependent compatibility check" has been eliminated in Ada 95. Any checking on subcomponents is performed when (and if) an object is created.

**Discussion:** There is no need to define compatibility with a constrained discriminated subtype, because one is not allowed to constrain it again.

A composite value satisfies a discriminant constraint if and only if each discriminant of the composite value has the value imposed by the discriminant constraint.

For the elaboration of a discriminant constraint, the expressions in the discriminant associations are evaluated in an arbitrary order and converted to the type of the associated discriminant (which might raise Constraint_Error — see 4.6); the expression of a named association is evaluated (and converted) once for each associated discriminant. The result of each evaluation and conversion is the value imposed by the constraint for the associated discriminant.

**Reason:** We convert to the type, not the subtype, so that the definition of compatibility of discriminant constraints is not vacuous.

**NOTES**

59 The rules of the language ensure that a discriminant of an object always has a value, either from explicit or implicit initialization.

**Discussion:** Although it is illegal to constrain a class-wide tagged subtype, it is possible to have a partially constrained class-wide subtype: If the subtype S is defined by T(A => B), then S'Class is partially constrained in the sense that objects of subtype S'Class have to have discriminants corresponding to A equal to B, but there can be other discriminants defined in extensions that are not constrained to any particular value.

**Examples**

Examples (using types declared above in subclause 3.7):

| Large   | Buffer(200); | constrained, always 200 characters |
| Message | Buffer;      | unconstrained, initially 100 characters |
| Basis   | Square(5);  | constrained, always 5 by 5         |
| Illegal | Square;     | illegal, a Square has to be constrained |

**Inconsistencies With Ada 83**

Dependent compatibility checks are no longer performed on subtype declaration. Instead they are deferred until object creation (see 3.3.1). This is upward compatible for a program that does not raise Constraint_Error.

**Wording Changes From Ada 83**

Everything in RM83-3.7.2(7-12), which specifies the initial values for discriminants, is now redundant with 3.3.1, 6.4.1, 8.5.1, and 12.4. Therefore, we don’t repeat it here. Since the material is largely intuitive, but nevertheless complicated to state formally, it doesn’t seem worth putting it in a "NOTE."

**Incompatibilities With Ada 95**

The Corrigendum added a restriction on discriminant constraints for general access subtypes. Such constraints are prohibited if the designated type can be treated as constrained somewhere. 
in the program. Ada 2005 goes further and prohibits such discriminant constraints if the designated type has (or might have, in the case of a formal type) defaults for its discriminants. The use of general access subtypes is rare, and this eliminates a boatload of problems that required many restrictions on the use of aliased objects and components (now lifted). Similarly, Ada 2005 prohibits discriminant constraints on any access type whose designated type has a partial view that is constrained. Such a type will not be constrained in the heap to avoid privacy problems. Again, the use of such subtypes is rare (they can only happen within the package and its child units).

**Wording Changes from Ada 2005**

\{AI05-0041-1\} **Correction:** Revised the rules on access subtypes having discriminant constraints to depend on the “known to be constrained” rules. This centralizes the rules so that future fixes need to be made in only one place, as well as fixing bugs in obscure cases.

\{AI05-0102-1\} **Correction:** Moved implicit conversion Legality Rule to 8.6.

### 3.7.2 Operations of Discriminated Types

[If a discriminated type has default_expressions for its discriminants, then unconstrained variables of the type are permitted, and the discriminants of such a variable can be changed by assignment to the variable. For a formal parameter of such a type, an attribute is provided to determine whether the corresponding actual parameter is constrained or unconstrained.]

**Static Semantics**

For a prefix A that is of a discriminated type [(after any implicit dereference)], the following attribute is defined:

\[\text{A'Constrained}\]

Yields the value True if A denotes a constant, a value, a tagged object, or a constrained variable, and False otherwise.

**Implementation Note:** \{AI05-0214-1\} This attribute is primarily used on parameters, to determine whether the discriminants can be changed as part of an assignment. The Constrained attribute is statically True for in parameters. For in out and out parameters of a discriminated type, the value of this attribute needs to be passed as an implicit parameter, in general. However, if the type is tagged or does not have defaults for its discriminants, the attribute is statically True, so no implicit parameter is needed. Parameters of a limited untagged type with defaulted discriminants need this implicit parameter, unless there are no nonlimited views, because they might be passed to a subprogram whose body has visibility on a nonlimited view of the type, and hence might be able to assign to the object and change its discriminants.

**Reason:** \{AI05-0214-1\} All tagged objects are known to be constrained (as nonlimited tagged types cannot have discriminant defaults, and limited tagged objects are immutably limited), and are always considered constrained by this attribute to avoid distributed overhead for parameters of limited classwide types, as limited tagged objects may technically be unconstrained if they use defaulted discriminants. Such objects still cannot have their discriminants changed, as assignment is not supported for them, so there is no use for this attribute that would justify the overhead of passing it with all classwide parameters.

**Discussion:** \{AI05-0005-1\} \{AI05-0214-1\} If the type of A is a type derived from an untagged partial view of a tagged type such that it is not a tagged type, then A is not considered a tagged object, and A'Constrained can return either True or False depending on the nature of the object.

**Erroneous Execution**

The execution of a construct is erroneous if the construct has a constituent that is a name denoting a subcomponent that depends on discriminants, and the value of any of these discriminants is changed by this execution between evaluating the name and the last use (within this execution) of the subcomponent denoted by the name.

**Ramification:** This rule applies to assignment_statements, calls (except when the discriminant-dependent subcomponent is an in parameter passed by copy), indexed_components, and slices. Ada 83 only covered the first two cases. AI83-00585 pointed out the situation with the last two cases. The cases of object_renaming_declarations and generic formal in out objects are handled differently, by disallowing the situation at compile time.
Extensions to Ada 83

For consistency with other attributes, we are allowing the prefix of Constrained to be a value as well as an object of a discriminated type, and also an implicit dereference. These extensions are not important capabilities, but there seems no reason to make this attribute different from other similar attributes. We are curious what most Ada 83 compilers do with F(1).X’Constrained.

We now handle in a general way the cases of erroneousness identified by AI83-00585, where the prefix of an indexed_component or slice is discriminant-dependent, and the evaluation of the index or discrete range changes the value of a discriminant.

Wording Changes from Ada 83

We have moved all discussion of erroneous use of names that denote discriminant-dependent subcomponents to this subclause. In Ada 83, it used to appear separately under assignment_statements and subprogram calls.

Wording Changes from Ada 2005

{AI05-0214-1} A’Constrained is now defined to return True for any A that is a tagged object. This doesn’t change the result for any A allowed by previous versions of Ada; the change is necessary to avoid unnecessary overhead for limited tagged parameters.

3.8 Record Types

A record object is a composite object consisting of named components. The value of a record object is a composite value consisting of the values of the components.

Syntax

record_type_definition ::= [[abstract] tagged] [limited] record_definition

record_definition ::= record
  component_list end record
| null record

component_list ::= component_item {component_item}
| {component_item} variant_part
| null;

{8652/0009} {AI95-00137-01} component_item ::= 

component_declaration | aspect_clause representation_clause

{AI05-0183-1} component_declaration ::= 
  defining_identifier_list : component_definition [:= default_expression]
  [aspect_specification];

Name Resolution Rules

The expected type for the default_expression, if any, in a component_declaration is the type of the component.

Legality Rules

This paragraph was deleted. {AI95-00287-01} A default_expression is not permitted if the component is of a limited type.

{AI95-00366-01} Each component_declaration declares a component of the record type. Besides components declared by component_declarations, the components of a record type include any
components declared by discriminant_specifications of the record type declaration. [The identifiers of all components of a record type shall be distinct.]

Proof: \{AI05-0299-1\} The identifiers of all components of a record type have to be distinct because they are all declared immediately within the same declarative region. See ClauseSection 8.

Within a type_declaration, a name that denotes a component, protected subprogram, or entry of the type is allowed only in the following cases:

- \{AI05-0004-1\} \{AI05-0295-1\} A name that denotes any component, protected subprogram, or entry is allowed within an aspect_specification, an operational item, or a representation item that occurs within the declaration of the composite type.

- \{AI05-0264-1\} A name that denotes a noninherited discriminant is allowed within the declaration of the type, but not within the discriminant_part. If the discriminant is used to define the constraint of a component, the bounds of an entry family, or the constraint of the parent subtype in a derived_type_definition, then its name shall appear alone as a direct_name (not as part of a larger expression or expanded name). A discriminant shall not be used to define the constraint of a scalar component.

Reason: The penultimate restriction simplifies implementation, and allows the outer discriminant and the inner discriminant or bound to possibly share storage.

Ramification: Other rules prevent such a discriminant from being an inherited one.

Discussion: Note that a discriminant can be used to define the constraint for a component that is of an access-to-composite type.

Reason: \{AI95-00373-01\} The above rules, and a similar one in 6.1 for formal parameters, are intended to allow initializations of components or parameters to occur in a (nearly) arbitrary order — whatever order is most efficient (subject to the restrictions of 3.3.1), since one default_expression cannot depend on the value of another one. They also prevent circularities.

Ramification: \{AI05-0295-1\} Inherited discriminants are not allowed to be denoted, except within aspect_specifications and representation items. However, the discriminant_selector_name of the parent subtype_indication is allowed to denote a discriminant of the parent.

If the name of the current instance of a type (see 8.6) is used to define the constraint of a component, then it shall appear as a direct_name that is the prefix of an attribute_reference whose result is of an access type, and the attribute_reference shall appear alone.

Reason: This rule allows T'Access or T'Unchecked_Access, but disallows, for example, a range constraint (1..T'Size). Allowing things like (1..T'Size) would mean that a per-object constraint could affect the size of the object, which would be bad.

Static Semantics

\{AI95-00318-02\} \{AI05-0004-1\} If a record_type_definition record_type_declaration includes the reserved word limited, the type is called an explicitly limited record type.

The component_definition of a component_declaration defines the (nominal) subtype of the component. If the reserved word aliased appears in the component_definition, then the component is aliased (see 3.10).

Ramification: \{AI95-00363-01\} In this case, the nominal subtype cannot be an unconstrained discriminated subtype. See 3.6.

If the component_list of a record type is defined by the reserved word null and there are no discriminants, then the record type has no components and all records of the type are null records. A record_definition of null record is equivalent to record null; end record.

Ramification: This short-hand is available both for declaring a record type and a record extension — see 3.9.1.
The elaboration of a `record_type_definition` creates the record type and its first subtype, and consists of the elaboration of the `record_definition`. The elaboration of a `record_definition` consists of the elaboration of its `component_list`, if any.

The elaboration of a `component_list` consists of the elaboration of the `component_items` and `variant_part`, if any, in the order in which they appear. The elaboration of a `component_declaration` consists of the elaboration of the `component_definition`.

**Discussion:** If the `defining_identifier_list` has more than one `defining_identifier`, we presume here that the transformation explained in 3.3.1 has already taken place. Alternatively, we could say that the `component_definition` is elaborated once for each `defining_identifier` in the list.

```plaintext
{8652/0002} {AI95-00171-01} {AI95-00230-01}
Within the definition of a composite type, if a `component_definition` or `discrete_subtype_definition` (see 9.5.2) includes a name that denotes a discriminant of the type, or that is an `attribute_reference` whose prefix denotes the current instance of the type, the expression containing the name is called a per-object expression, and the constraint or range being defined is called a per-object constraint. For the elaboration of a `component_definition` of a `component_declaration` or the `discrete_subtype_definition` of an `entry_declaration` for an entry family (see 9.5.2), if the component subtype is defined by an `access_definition` or if the constraint or range of the subtype indication or `discrete_subtype_definition` is not a per-object constraint, then the `access_definition`, `subtype_indication`, or `discrete_subtype_definition` is elaborated. On the other hand, if the constraint or range is a per-object constraint, then the elaboration consists of the evaluation of any included expression that is not part of a per-object expression. Each such expression is evaluated once unless it is part of a named association in a discriminant constraint, in which case it is evaluated once for each associated discriminant.
```

**Discussion:** The evaluation of other expressions that appear in `component_definitions` and `discrete_subtype_definitions` is performed when the type definition is elaborated. The evaluation of expressions that appear as default expressions is postponed until an object is created. Expressions in representation items that appear within a composite type definition are evaluated according to the rules of the particular representation item.

**NOTES**

60 A `component_declaration` with several identifiers is equivalent to a sequence of single `component_declarations`, as explained in 3.3.1.

61 The default_expression of a record component is only evaluated upon the creation of a default-initialized object of the record type (presuming the object has the component, if it is in a `variant_part` — see 3.3.1).

62 The subtype defined by a `component_definition` (see 3.6) has to be a definite subtype.

63 If a record type does not have a `variant_part`, then the same components are present in all values of the type.

64 A record type is limited if it has the reserved word `limited` in its definition, or if any of its components are limited (see 7.5).

65 The predefined operations of a record type include membership tests, qualification, and explicit conversion. If the record type is nonlimited, they also include assignment and the predefined equality operators.

66 {AI95-00287-01} A component of a record can be named with a selected_component. A value of a record can be specified with a `record_aggregate`, unless the record type is limited.
Examples

Examples of record type declarations:

```ada
type Date is
  record
    Day   : Integer range 1 .. 31;
    Month : Month_Name;
    Year  : Integer range 0 .. 4000;
  end record;

type Complex is
  record
    Re : Real := 0.0;
    Im : Real := 0.0;
  end record;
```

Examples of record variables:

```ada
Tomorrow, Yesterday : Date;
A, B, C : Complex;
```

```
-- both components of A, B, and C are implicitly initialized to zero
```

Extensions to Ada 83

31a The syntax rule for component_declaration is modified to use component_definition (instead of component_subtype_definition). The effect of this change is to allow the reserved word aliased before the component_subtype_definition.

31b A short-hand is provided for defining a null record type (and a null record extension), as these will be more common for abstract root types (and derived types without additional components).

31c The syntax rule for record_type_definition is modified to allow the reserved words tagged and limited. Tagging is new. Limitedness is now orthogonal to privateness. In Ada 83 the syntax implied that limited private was sort of more private than private. However, limitedness really has nothing to do with privateness; limitedness simply indicates the lack of assignment capabilities, and makes perfect sense for nonprivate types such as record types.

Wording Changes from Ada 83

31d1 [8652/0009] {AI95-00137-01} The syntax rules now allow aspect_clause, representation_clauses to appear in a record_definition. This is not a language extension, because Legality Rules prevent all language-defined representation clauses from appearing there. However, an implementation-defined attribute_definition_clause could appear there. The reason for this change is to allow the rules for aspect_clause, representation_clauses and representation pragmas to be as similar as possible.

31e2 {AI95-00287-01} Record components can have an anonymous access type.

31f2 {AI95-00287-01} Limited components can be initialized, so long as the expression is one that allows building the object in place (such as an aggregate or function_call).

Wording Changes from Ada 95

31g2 [8652/0002] {AI95-00171-01} Corrigendum: Improved the description of the elaboration of per-object constraints.

31h2 [8652/0009] {AI95-00137-01} Corrigendum: Changed representation clauses to aspect clauses to reflect that they are used for more than just representation.

31i2 {AI95-00318-02} Defined explicitly limited record type to use in other rules.

Extensions to Ada 2005

31j3 {AI05-0183-1} An optional aspect_specification can be used in a component_declaration. This is described in 13.1.1.

3.8.1 Variant Parts and Discrete Choices

A record type with a variant_part specifies alternative lists of components. Each variant defines the components for the value or values of the discriminant covered by its discrete_choice_list.
**Discussion:** Discrete_choice_lists and discrete_choices are said to cover values as defined below; which discrete_choice_list covers a value determines which of various alternatives is chosen. These are used in variant_parts, array_aggregates, and case_statements.

**Language Design Principles**

The definition of “cover” in this subclause and the rules about discrete choices are designed so that they are also appropriate for array aggregates and case statements.

The rules of this subclause intentionally parallel those for case statements.

**Syntax**

```
variant_part ::= 
case discriminant_direct_name is 
  variant
  {variant}
end case;
variant ::= 
  when discrete_choice_list =>
  component_list
  discrete_choice_list ::= discrete_choice { | discrete_choice}
{AI05-0153-3} {AI05-0158-1} discrete_choice ::= 
  choice_expression | discrete_subtype_indication | range | others
```

**Name Resolution Rules**

The discriminant_direct_name shall resolve to denote a discriminant (called the discriminant of the variant_part) specified in the known_discriminant_part of the full_type_declaration that contains the variant_part. The expected type for each discrete_choice in a variant is the type of the discriminant of the variant_part.

Ramification: A full_type_declaration with a variant_part has to have a (new) known_discriminant_part; the discriminant of the variant_part cannot be an inherited discriminant.

**Legality Rules**

The discriminant of the variant_part shall be of a discrete type.

Ramification: It shall not be of an access type, named or anonymous.

{AI05-0153-3} The choice_expression, subtype_indications, and range_expressions and discrete_ranges given as discrete_choices in a variant_part shall be static. The discrete_choice others shall appear alone in a discrete_choice_list, and such a discrete_choice_list, if it appears, shall be the last one in the enclosing construct.

A discrete_choice is defined to cover a value in the following cases:

- {AI05-0262-1} A discrete_choice that is a choice_expression covers a value if the value equals the value of the choice_expression converted to the expected type.
- {AI05-0153-3} {AI05-0262-1} A discrete_choice that is a subtype_indication covers all values (possibly none) that belong to the subtype and that satisfy the static predicate of the subtype (see 3.2.4).

Ramification: {AI05-0262-1} A dynamic predicate is never allowed in this case (for variants, case_statements, and case_expressions, a subtype with a dynamic predicate isn't static and thus isn't allowed in a discrete_choice, and for a choice in an array_aggregate, a dynamic predicate is explicitly disallowed — see 3.2.4).

- {AI05-0153-3} A discrete_choice that is a range discrete_range covers all values (possibly none) that belong to the range.
3.8.1 Variant Parts and Discrete Choices

The `discrete_choice others` covers all values of its expected type that are not covered by previous `discrete_choice_list`s of the same construct.

**Ramification:** For case statements, this includes values outside the range of the static subtype (if any) to be covered by the choices. It even includes values outside the base range of the case expression’s type, since values of numeric types (and undefined values of any scalar type?) can be outside their base range.

A `discrete_choice_list` covers a value if one of its `discrete_choice`s covers the value.

The possible values of the discriminant of a `variant_part` shall be covered as follows:

- **{AI05-0153-3} {AI05-0188-1} {AI05-0262-1}** If the discriminant is of a static constrained scalar subtype, then, except within an instance of a generic unit, each non-`others` `discrete_choice` shall cover only values in that subtype that satisfy its predicate, and each value of that subtype that satisfies its predicate shall be covered by some `discrete_choice` [(either explicitly or by `others`)];

  **Reason:** The exemption for a discriminated type declared in an instance allows the following example:

  ```ada
generic
  type T is new Integer;
package G is
  type Rec (Discrim : T) is record
    case Discrim is
      when -10 .. -1 =>
        Foo : Float;
      when others =>
        null;
  end case;
end record;
end G;
package I is new G (Natural); -- Legal
```

- **{AI05-0264-1}** If the type of the discriminant is a descendant of a generic formal scalar type, then the `variant_part` shall have an `others` `discrete_choice`;

  **Reason:** The base range is not known statically in this case.

- Otherwise, each value of the base range of the type of the discriminant shall be covered [(either explicitly or by `others`)].

Two distinct `discrete_choice`s of a `variant_part` shall not cover the same value.

**Static Semantics**

If the component_list of a variant is specified by `null`, the variant has no components.

The discriminating of a `variant_part` is said to govern the `variant_part` and its variants. In addition, the discriminating of a derived type governs a `variant_part` and its variants if it corresponds (see 3.7) to the discriminating of the `variant_part`.

**Dynamic Semantics**

A record value contains the values of the components of a particular variant only if the value of the discriminating governing the `variant` is covered by the `discrete_choice_list` of the variant. This rule applies in turn to any further variant that is, itself, included in the component_list of the given variant.

**Implementation Note:** This is not a “check”; it cannot be suppressed. However, in most cases it is not necessary to generate any code to raise this exception. A test is needed (and can fail) in the case where the discriminating subtype has a Static_Predicate specified, it also has predicate checking disabled, and the discriminating governs a `variant_part` which lacks a `when others` choice.
The test also could fail for a static discriminant subtype with range checking suppressed and the discriminant governs a variant_part which lacks a when others choice. But execution is erroneous if a range check that would have failed is suppressed (see 11.5), so an implementation does not have to generate code to check this case. (An unchecked failed predicate does not cause erroneous execution, so the test is required in that case.)

Like the checks associated with a per-object constraint, this test is not made during the elaboration of a subtype_indication.

The elaboration of a variant_part consists of the elaboration of the component_list of each variant in the order in which they appear.

Examples

Example of record type with a variant part:

```ada
type Device is (Printer, Disk, Drum);
type State is (Open, Closed);
type Peripheral(Unit : Device := Disk) is record
    Status : State;
    case Unit is
        when Printer =>
            Line_Count : Integer range 1 .. Page_Size;
        when others =>
            Cylinder   : Cylinder_Index;
            Track      : Track_Number;
    end case;
end record;
```

Examples of record subtypes:

```ada
subtype Drum_Unit is Peripheral(Drum);
subtype Disk_Unit is Peripheral(Disk);
```

Examples of constrained record variables:

```ada
Writer   : Peripheral(Unit  => Printer);
Archive  : Disk_Unit;
```

Extensions to Ada 83

In Ada 83, the discriminant of a variant_part is not allowed to be of a generic formal type. This restriction is removed in Ada 95; an others discrete_choice is required in this case.

Wording Changes from Ada 83

The syntactic category choice is removed. The syntax rules for variant, array_aggregate, and case_statement now use discrete_choice_list or discrete_choice instead. The syntax rule for record_aggregate now defines its own syntax for named associations.

Extensions to Ada 2005

```ada
subtype with static predicates can be used in discrete_choices, and the coverage rules are modified to respect the predicates.
```
3.9 Tagged Types and Type Extensions

[ Tagged types and type extensions support object-oriented programming, based on inheritance with extension and run-time polymorphism via dispatching operations. ]

Language Design Principles

1.a/2

AI95-00251-01 The intended implementation model is for the static portion of a tag to be represented as a pointer to a statically allocated and link-time initialized type descriptor. The type descriptor contains the address of the code for each primitive operation of the type. It probably also contains other information, such as might make membership tests convenient and efficient. Tags for nested type extensions must also have a dynamic part that identifies the particular elaboration of the type.

1.b

The primitive operations of a tagged type are known at its first freezing point; the type descriptor is laid out at that point. It contains linker symbols for each primitive operation; the linker fills in the actual addresses.

1.b.1/2

AI95-00251-01 Primitive operations of type extensions that are declared at a level deeper than the level of the ultimate ancestor from which they are derived can be represented by wrappers that use the dynamic part of the tag to call the actual primitive operation. The dynamic part would generally be some way to represent the static link or display necessary for making a nested call. One implementation strategy would be to store that information in the extension part of such nested type extensions, and use the dynamic part of the tag to point at it. (That way, the “dynamic” part of the tag could be static, at the cost of indirect access.)

1.b.2/2

AI95-00251-01 If the tagged type is descended from any interface types, it also will need to include “subtags” (one for each interface) that describe the mapping of the primitive operations of the interface to the primitives of the type. These subtags could directly reference the primitive operations (for faster performance), or simply provide the tag “slot” numbers for the primitive operations (for easier derivation). In either case, the subtags would be used for calls that dispatch through a class-wide type of the interface.

1.c

Other implementation models are possible.

1.d

The rules ensure that “dangling dispatching” is impossible; that is, when a dispatching call is made, there is always a body to execute. This is different from some other object-oriented languages, such as Smalltalk, where it is possible to get a run-time error from a missing method.

1.e/2

AI95-00251-01 Dispatching calls should be efficient, and should have a bounded worst-case execution time. This is important in a language intended for real-time applications. In the intended implementation model, a dispatching call involves calling indirect through the appropriate slot in the dispatch table. No complicated “method lookup” is involved although a call which is dispatching on an interface may require a lookup of the appropriate interface subtag.

1.f

The programmer should have the choice at each call site of a dispatching operation whether to do a dispatching call or a statically determined call (i.e. whether the body executed should be determined at run time or at compile time).

1.g

The same body should be executed for a call where the tag is statically determined to be T’Tag as for a dispatching call where the tag is found at run time to be T’Tag. This allows one to test a given tagged type with statically determined calls, with some confidence that run-time dispatching will produce the same behavior.

1.h

All views of a type should share the same type descriptor and the same tag.

1.i

The visibility rules determine what is legal at compile time; they have nothing to do with what bodies can be executed at run time. Thus, it is possible to dispatch to a subprogram whose declaration is not visible at the call site. In fact, this is one of the primary facts that gives object-oriented programming its power. The subprogram that ends up being dispatched to by a given call might even be designed long after the call site has been coded and compiled.

1.j

Given that Ada has overloading, determining whether a given subprogram overrides another is based both on the names and the type profiles of the operations.

1.k/2

AI95-00401-01 When a type extension is declared, if there is any place within its immediate scope where a certain subprogram of the parent or progenitor is visible, then a matching subprogram should override. If there is no such place, then a matching subprogram should be totally unrelated, and occupy a different slot in the type descriptor. This
is important to preserve the privacy of private parts; when an operation declared in a private part is inherited, the inherited version can be overridden only in that private part, in the package body, and in any children of the package.

If an implementation shares code for instances of generic bodies, it should be allowed to share type descriptors of tagged types declared in the generic body, so long as they are not extensions of types declared in the specification of the generic unit.

**Static Semantics**

\{AI95-00345-01\} A record type or private type that has the reserved word *tagged* in its declaration is called a *tagged type*. In addition, an interface type is a tagged type, as is a task or protected type derived from an interface (see 3.9.4). When deriving from a tagged type, additional components may be defined. As for any derived type, additional primitive subprograms may be defined, and inherited primitive subprograms may be overridden. The derived type is called an *extension* of its ancestor *type*. Every type extension is also a tagged type, and is either a *record extension* or a *private extension* of some other tagged type. A record extension is defined by a derived_type_definition with a record_extension_part. A private extension, which is a partial view of a record extension, can be declared in the visible part of a package (see 7.3) or in a generic formal part (see 12.5.1).

\{AI95-00345-01\} Every type extension is also a tagged type, and is a record extension or a private extension of some other tagged type, or a noninterface synchronized tagged type (see 3.9.4). A record extension is defined by a derived_type_definition with a record_extension_part (see 3.9.1), which may include the definition of additional components. A private extension, which is a partial view of a record extension or of a synchronized tagged type, can be declared in the visible part of a package (see 7.3) or in a generic formal part (see 12.5.1).

**Glossary entry:** The objects of a tagged type have a run-time type tag, which indicates the specific type with which the object was originally created. An operand of a class-wide tagged type can be used in a dispatching call; the tag indicates which subprogram body to invoke. Nondispatching calls, in which the subprogram body to invoke is determined at compile time, are also allowed. Tagged types may be extended with additional components.

**Ramification:** \{AI95-00218-03\} If a tagged type is declared other than in a package_specification, it is impossible to add new primitive subprograms for that type, although it can inherit primitive subprograms, and those can be overridden. If the user incorrectly thinks a certain subprogram is primitive when it is not, and tries to call it with a dispatching call, an error message will be given at the call site. Similarly, by using an overriding_indicator (see 6.1), the user can declare that a subprogram is intended to be overriding, and get an error message when they made a mistake. The use of overriding_indicators is highly recommended in new code that does not need to be compatible with Ada 95.

\{AI95-00344-01\} Note that the accessibility rules imply that a tagged type declared in a library_package_specification cannot be extended in a nested subprogram or task body.

An object of a tagged type has an associated (run-time) *tag* that identifies the specific tagged type used to create the object originally. The tag of an operand of a class-wide tagged type *T* class controls which subprogram body is to be executed when a primitive subprogram of type *T* is applied to the operand (see 3.9.2); using a tag to control which body to execute is called *dispatching*.

\{AI95-00344-01\} The tag of a specific tagged type identifies the full_type_declaration of the type, and for a type extension, is sufficient to uniquely identify the type among all descendants of the same ancestor. If a declaration for a tagged type occurs within a generic_package_declaration, then the corresponding type declarations in distinct instances of the generic package are associated with distinct tags. For a tagged type that is local to a generic package body and with all of its ancestors (if any) also local to the generic body, the language does not specify whether repeated instantiations of the generic body result in distinct tags.

This paragraph was deleted. **Reason:** \{AI95-00344-01\} This eases generic code sharing.

**Implementation Note:** \{AI95-00344-01\} In most cases, a tag need only identify a particular tagged type declaration, and can therefore be a simple link-time-known address. However, for tag checks (see 3.9.2) it is essential that each descendant (that currently exists) of a given type have a unique tag. Hence, for types declared in shared generic bodies
where an ancestor comes from outside the generic, or for types declared at a deeper level than an ancestor, the tag needs to be augmented with some kind of dynamic descriptor (which may be a static link, global display, instance descriptor pointer, or combination). This implies that type Tag may need to be two words, the second of which is normally null, but in these identified special cases needs to include a static link or equivalent. Within an object of one of these types with a two-word tag, the two parts of the tag would typically be separated, one part as the first word of the object, the second placed in the first extension part that corresponds to a type declared more nested than its parent or declared in a shared generic body when the parent is declared outside. Alternatively, by using an extra level of indirection, the type Tag could remain a single-word.

{AI95-00344-01} For types that are not type extensions (even for ones declared in nested scopes), we do not require that the language does not specify whether repeated elaborations of the same full_type_declaration correspond to distinct tags. This was done so that Ada 2005 implementations of tagged types could maintain representation compatibility with Ada 95 implementations. Only type extensions that were not allowed in Ada 95 require additional information with the tag in most cases, we expect that all elaborations will correspond to the same tag, since the tag will frequently be the address (or index) of a statically allocated type-descriptor. However, with shared generics, the type descriptor might have to be allocated on a per-instance basis, which in some implementation models implies per-elaboration of the instantiation.

To be honest: {AI95-00344-01} The wording “is sufficient to uniquely identify the type among all descendants of the same ancestor” only applies to types that currently exist. It is not necessary to distinguish between descendants that currently exist, and descendants of the same type that no longer exist. For instance, the address of the stack frame of the subprogram that created the tag is sufficient to meet the requirements of this rule, even though it is possible, after the subprogram returns, that a later call of the subprogram could have the same stack frame and thus have an identical tag.

The following language-defined library package exists:

```ada
package Ada.Tags is
  type Tag is private;
  pragma Preelaborable_Initialization(Tag);
  pragma Preelaborate(Tags);

  No_Tag : constant Tag := No_Tag;

  function Expanded_Name(T : Tag) return String;
  function Wide_Expanded_Name(T : Tag) return Wide_String;
  function Wide_Wide_Expanded_Name(T : Tag) return Wide_Wide_String;
  function External_Tag(T : Tag) return String;
  function Internal_Tag(T : Tag) return Tag;

  function Descendant_Tag(External : String; Ancestor : Tag) return Tag;
  function Is_Descendant_At_Same_Level(Ancestor : Tag) return Boolean;
  function Parent_Tag(T : Tag) return Tag;
  function Tag_Array is array (Positive range <>) of Tag;
  function Interface_Ancestor_Tags(T : Tag) return Tag_Array;

  function Is_Abstract(T : Tag) return Boolean;
  constant Tag_Error : exception;

private
  ... -- not specified by the language
end Ada.Tags;
```

Reason: Tag is a nonlimited, definite subtype, because it needs the equality operators, so that tag checking makes sense. Also, equality, assignment, and object declaration are all useful capabilities for this subtype.

For an object X and a type T, “X’Tag = T’Tag” is not needed, because a membership test can be used. However, comparing the tags of two objects cannot be done via membership. This is one reason to allow equality for type Tag.

{AI95-00260-02} No Tag is the default initial value of type Tag.

Reason: {AI95-00260-02} This is similar to the requirement that all access values be initialized to null.

{AI95-00400-01} The function Wide_Wide_Expanded_Name returns the full expanded name of the first subtype of the specific type identified by the tag, in upper case, starting with a root library unit. The result is implementation defined if the type is declared within an unnamed block_statement.
The function `Expanded_Name` (respectively, `Wide_Expanded_Name`) returns the same sequence of graphic characters as that defined for `Wide_Expanded_Name`, if all the graphic characters are defined in `Character` (respectively, `Wide_Character`); otherwise, the sequence of characters is implementation defined, but no shorter than that returned by `Wide_Expanded_Name` for the same value of the argument.

**Implementation defined:** The sequence of characters of the value returned by `Tags.Expanded_Name` (respectively, `Tags.Wide_Expanded_Name`) when some of the graphic characters of `Tags.Wide_Expanded_Name` are not defined in `Character` (respectively, `Wide_Character`).

The function `External_Tag` returns a string to be used in an external representation for the given tag. The call `External_Tag(S'Tag)` is equivalent to the `attribute_reference` `S'External_Tag` (see 13.3).

**Reason:** It might seem redundant to provide both the function `External_Tag` and the attribute `External_Tag`. The function is needed because the attribute can't be applied to values of type Tag. The attribute is needed so that it can be specified via an `attribute_definition_clause`.

The string returned by the functions `Expanded_Name`, `Wide_Expanded_Name`, `Wide_Wide_Expanded_Name`, and `External_Tag` has lower bound 1.

The function `Internal_Tag` returns the tag that corresponds to the given external tag, or raises `Tag_Error` if the given string is not the external tag for any specific type of the partition. `Tag_Error` is also raised if the specific type identified is a library-level type whose tag has not yet been created (see 13.14).

**Reason:** The check for uncreated library-level types prevents a reference to the type before execution reaches the freezing point of the type. This is important so that `TClass'Input` or an instance of `Tags.Generic_Dispatching_Constructor` do not try to create an object of a type that hasn't been frozen (which might not have yet elaborated its constraints). We don't require this behavior for non-library-level types as the tag can be created multiple times and possibly multiple copies can exist at the same time, making the check complex.

The function `Descendant_Tag` returns the (internal) tag for the type that corresponds to the given external tag and is both a descendant of the type identified by the Ancestor tag and has the same accessibility level as the identified ancestor. `Tag_Error` is raised if `External` is not the external tag for such a type. `Tag_Error` is also raised if the specific type identified is a library-level type whose tag has not yet been created, or if the given external tag identifies more than one type that has the appropriate Ancestor and accessibility level.

**Reason:** `Descendant_Tag` is used by `TClass'Input` to identify the type identified by an external tag. Because there can be multiple elaborations of a given type declaration, `Internal_Tag` does not have enough information to choose a unique such type. `Descendant_Tag` does not return the tag for types declared at deeper accessibility levels than the ancestor because there could be ambiguity in the presence of recursion or multiple tasks. `Descendant_Tag` can be used in constructing a user-defined replacement for `TClass'Input`.

**Rules for specifying external tags will usually prevent an external tag from identifying more than one type. However, an external tag can identify multiple types if a generic body contains a derivation of a tagged type declared outside of the generic, and there are multiple instances at the same accessibility level as the type. (The Standard allows default external tags to not be unique in this case.)**

The function `Is_Descendant_At_Same_Level` returns `True` if the `Descendant_Tag` identifies a type that is both a descendant of the type identified by Ancestor and at the same accessibility level. If not, it returns `False`.

**Reason:** `Is_Descendant_At_Same_Level` (or something similar to it) is used by `TClass'Output` to determine whether the item being written is at the same accessibility level as T. It may be used to determine prior to using `TClass'Output` whether `Tag_Error` will be raised, and also can be used in constructing a user-defined replacement for `TClass'Output`.

For the purposes of the dynamic semantics of functions `Descendant_Tag` and `Is_Descendant_At_Same_Level`, a tagged type `T2` is a descendant of a type `T1` if it is the same as `T1`, or if...
its parent type or one of its progenitor types is a descendant of type T1 by this rule[, even if at the point of 
the declaration of T2, one of the derivations in the chain is not visible].

Discussion: In other contexts, “descendant” is dependent on visibility, and the particular view a derived type has of its 
parent type. See 7.3.1.

{A195-00260-02} The function Parent_Tag returns the tag of the parent type of the type whose tag is T. If 
the type does not have a parent type (that is, it was not declared by a derived_type_declaration), then 
No_Tag is returned.

Ramification: The parent type is always the parent of the full type; a private extension appears to define a parent type, 
but it does not (only the various forms of derivation do that). As this is a run-time operation, ignoring privateness is 
OK.

{A195-00405-01} The function Interface_Ancestor_Tags returns an array containing the tag of each 
interface ancestor type of the type whose tag is T, other than T itself. The lower bound of the returned 
array is 1, and the order of the returned tags is unspecified. Each tag appears in the result exactly once.[ If 
the type whose tag is T has no interface ancestors, a null array is returned.]

Ramification: The result of Interface_Ancestor_Tags includes the tag of the parent type, if the parent is an interface. 
Indirect interface ancestors are included in the result of Interface_Ancestor_Tags. That’s because where an interface 
appears in the derivation tree has no effect on the semantics of the type; the only interesting property is whether the 
type has an interface as an ancestor.

{A105-0173-1} The function Is_Abstract returns True if the type whose tag is T is abstract, and False 
otherwise.

For every subtype S of a tagged type T (specific or class-wide), the following attributes are defined:

S'Class S'Class denotes a subtype of the class-wide type (called T'Class in this International Standard) 
for the class rooted at T (or if S already denotes a class-wide subtype, then S'Class is the same 
as S).

S'Class is unconstrained. However, if S is constrained, then the values of S'Class are only 
those that when converted to the type T belong to S.

Ramification: This attribute is defined for both specific and class-wide subtypes. The definition is such that 
S'Class=T'Class is the same as S'Class. 
Note that if S is constrained, S'Class is only partially constrained, since there might be additional discriminants added 
in descendants of T which are not constrained.

Reason: {A195-00326-01} The Class attribute is not defined for untagged subtypes (except for incomplete types and 
private types whose full view is tagged — see 11.2 and 7.3.1) so as to preclude implicit conversion in the 
absence of run-time type information. If it were defined for untagged subtypes, it would correspond to the concept of 
universal types provided for the predefined numeric classes.

S'Tag S'Tag denotes the tag of the type T (or if T is class-wide, the tag of the root type of the 
corresponding class). The value of this attribute is of type Tag.

Reason: S'Class'Tag equals S'Tag, to avoid generic contract model problems when S'Class is the actual type associated 
with a generic formal derived type.

Given a prefix X that is of a class-wide tagged type [(after any implicit dereference)], the following 
attribute is defined:

X'Tag X'Tag denotes the tag of X. The value of this attribute is of type Tag.

Reason: X'Tag is not defined if X is of a specific type. This is primarily to avoid confusion that might result about 
whether the Tag attribute should reflect the tag of the type of X, or the tag of X. No such confusion is possible if X is 
of a class-wide type.

{A195-00260-02} {A195-00441-01} The following language-defined generic function exists:
The tag associated with an object of a tagged type is determined as follows:

- The tag of a stand-alone object, a component, or an aggregate of a specific tagged type \( T \) identifies \( T \).
  
  **Discussion:** The tag of a formal parameter of type \( T \) is not necessarily the tag of \( T \), if, for example, the actual was a type conversion.

- The tag of an object created by an allocator for an access type with a specific designated tagged type \( T \), identifies \( T \).
  
  **Discussion:** The tag of an object designated by a value of such an access type might not be \( T \), if, for example, the access value is the result of a type conversion.

- The tag of an object of a class-wide tagged type is that of its initialization expression.
  
  **Ramification:** The tag of an object (even a class-wide one) cannot be changed after it is initialized, since a “class-wide” assignment statement raises Constraint_Error if the tags don't match, and a “specific” assignment statement does not affect the tag.

- The tag of the result returned by a function whose result type is a specific tagged type \( T \) identifies \( T \).
  
  **Implementation Note:** \{AI95-00318-02\} For a limited tagged type, the return object is “built in place” in the ultimate result object with the appropriate tag. This requires a run-time check for limited tagged types, since they are returned “by-reference.” For a nonlimited type, a new anonymous object with the appropriate tag is created as part of the function return, and then assigned the value of the return expression. See 6.5, “Return Statements”.

- The tag is preserved by type conversion and by parameter passing. The tag of a value is the tag of the associated object (see 6.2).

- An instance of Tags.Generic_Dispatching_Constructor raises Tag_Error if The_Tag does not represent a concrete descendant of \( T \) or if the innermost master (see 7.6.1) of this descendant is not also a master of the instance. Otherwise, it dispatches to the primitive function denoted by the formal
The tag check checks both that The_Tag is in T'Class, and that it is not abstract. These checks are similar to the ones required by streams for T'Class'Input (see 13.13.2). In addition, there is a check that the tag identifies a type declared on the current dynamic call chain, and not a more nested type or a type declared by another task. This check is not necessary for streams, because the stream attributes are declared at the same dynamic level as the type used.

### Ramification: One reason that a type might not exist in the partition is that the tag refers to a type whose declaration was elaborated as part of an execution of a subprogram body which has been left (see 7.6.1).

We exclude tags of library-level types from the current execution of the partition, because misuse of such tags should always be detected. T'Tag freezes the type (and thus creates the tag), and Internal_Tag and Descendant_Tag cannot return the tag of a library-level type that has not been created. All ancestors of a tagged type must be frozen no later than the (full) declaration of a type that uses them, so Parent_Tag and Interface_Ancestor_Tags cannot return a tag that has not been created. Finally, library-level types never cease to exist while the partition is executing. Thus, if the tag comes from a library-level type, there cannot be erroneous execution (the use of Descendant_Tag rather than Internal_Tag can help ensure that the tag is of a library-level type). This is also similar to the rules for T'Class'Input (see 13.13.2).

### Discussion: Ada 95 allowed Tag_Error in this case, or expected the functions to work. This worked because most implementations used tags constructed at link-time, and each elaboration of the same type_declaration produced the same tag. However, Ada 2005 requires at least part of the tags to be dynamically constructed for a type derived from a type at a shallower level. For dynamically constructed tags, detecting the error can be expensive and unreliable. To see this, consider a program containing two tasks. Task A creates a nested tagged type, passes the tag to task B (which saves it), and then terminates. The nested tag (if dynamic) probably will need to refer in some way to the stack frame for task A. If task B later tries to use the tag created by task A, the tag's reference to the stack frame of A probably is a dangling pointer. Avoiding this would require some sort of protected tag manager, which would be a bottleneck in a program's performance. Moreover, we'd still have a race condition; if task A terminated after the tag check, but before the tag was used, we'd still have a problem. That means that all of these operations would have to be serialized. That could be a significant performance drain, whether or not nested tagged types are ever used. Therefore, we allow execution to become erroneous as we do for other dangling pointers. If the implementation can detect the error, we recommend that Tag_Error be raised.

### Implementation Permissions

The implementation of Internal_Tag and Descendant_Tag functions in Ada.Tags may raise Tag_Error if no specific type corresponding to the string External_Tag passed as a parameter exists in the partition at the time the function is called. If there is no such type whose innermost master is a master of the point of the function call, then execution is erroneous.

### Reason: Locking would be required to ensure that the mapping of strings to tags never returned tags of types which no longer exist, because types can cease to exist (because they belong to another task, as described above) during the execution of these operations. Moreover, even if these functions did use locking, that would not prevent the type from ceasing to exist at the instant that the function returned. Thus, we do not require the overhead of locking. In most implementations, repeated elaborations of the same type_declaration will all produce the same tag. In such an implementation, Tag_Error will be raised in cases where the internal or external tag was passed from a different partition. However, some implementations might create a new tag value at run time for each elaboration of a type_declaration. In that case, Tag_Error could also be raised if the created type no longer exists because the subprogram containing it has returned, for example. We don't require the latter behavior, hence the word “may” in this rule.

### Implementation Advice

Internal_Tag should return the tag of a type, if one exists, whose innermost master is the master of the point of the function call.
Implementation Advice: Tags.Internal_Tag should return the tag of a type, if one exists, whose innermost master is the master of the point of the function call.

Reason: {AI95-00260-02} {AI95-00344-01} It's not helpful if Internal_Tag returns the tag of some type in another task when one is available in the task that made the call. We don't require this behavior (because it requires the same implementation techniques we decided not to insist on previously), but encourage it.

Discussion: {AI05-0113-1} There is no Advice for the result of Internal_Tag if no such type exists. In most cases, the Implementation Permission can be used to raise Tag_Error, but some other tag can be returned as well.

NOTES

67 A type declared with the reserved word tagged should normally be declared in a package_specification, so that new primitive subprograms can be declared for it.

68 Once an object has been created, its tag never changes.

69 Class-wide types are defined to have unknown discriminants (see 3.7). This means that objects of a class-wide type have to be explicitly initialized (whether created by an object_declaration or an allocator), and that aggregates have to be explicitly qualified with a specific type when their expected type is class-wide.

70 {AI95-00260-02} {AI95-00326-01} The capability provided by Tags.Generic_Dispatching_Constructor is sometimes known as a factory. If S denotes an untagged private type whose full type is tagged, then S'Class is also allowed before the full type definition, but only in the private part of the package in which the type is declared (see 7.3.1). Similarly, the Class attribute is defined for incomplete types whose full type is tagged, but only within the library unit in which the incomplete type is declared (see 3.10.1).

Examples

Examples of tagged record types:

```ada
type Point is tagged record
  X, Y : Real := 0.0;
end record;

type Expression is tagged null record;
-- Components will be added by each extension
```

Extensions to Ada 83

Tagged types are a new concept.

Inconsistencies With Ada 95

{AI95-00279-01} Amendment Correction: Added wording specifying that Internal_Tag must raise Tag_Error if the tag of a library-level type has not yet been created. Ada 95 gave an Implementation Permission to do this; we require it to avoid erroneous execution when streaming in an object of a library-level type that has not yet been elaborated. This is technically inconsistent; a program that used Internal_Tag outside of streaming and used a compiler that didn't take advantage of the Implementation Permission would not have raised Tag_Error, and may have returned a useful tag. (If the tag was used in streaming, the program would have been erroneous.) Since such a program would not have been portable to a compiler that did take advantage of the Implementation Permission, this is not a significant inconsistency.

{AI95-00417-01} We now define the lower bound of the string returned from [[Wide]Wide]Expanded_Name and External_Name. This makes working with the returned string easier, and is consistent with many other string-returning functions in Ada. This is technically an inconsistency; if a program depended on some other lower bound for the string returned from one of these functions, it could fail when compiled with Ada 2005. Such code is not portable even between Ada 95 implementations, so it should be very rare.

Incompatibilities With Ada 95

{AI95-00260-02} {AI95-00344-01} {AI95-00400-01} {AI95-00405-01} {AI05-0005-1} Constant No_Tag, and functions Parent_Tag, Interface_Ancestor_Tags, Descendant_Tag, Is_Descendant_At_Same_Level, Wide_Expanded_Name, and Wide_Wide_Expanded_Name are newly added to Ada.Tags. If Ada.Tags is referenced in a use_clause, and an entity E with the same defining_identifier as a new entity in Ada.Tags is defined in a package that is also referenced in a use_clause, the entity E may no longer be use-visible, resulting in errors. This should be rare and is easily fixed if it does occur.

Extensions to Ada 95

{AI95-00362-01} Ada.Tags is now defined to be preelaborated.

{AI95-00260-02} Generic function Tags.Generic_Dispatching_Constructor is new.
Wording Changes from Ada 95

3.9.1 Type Extensions

Language Design Principles

We want to make sure that we can extend a generic formal tagged type, without knowing its discriminants.

We don't want to allow components in an extension aggregate to depend on discriminants inherited from the parent value, since such dependence requires staticness in aggregates, at least for variants.

Syntax

record_extension_part ::= with record_definition

Legality Rules

The parent type of a record extension shall not be a class-wide type nor shall it be a synchronized tagged type (see 3.9.4). If the parent type or any progenitor is nonlimited, then each of the components of the record_extension_part shall be nonlimited. The accessibility level (see 3.10.2) of a record extension shall not be statically deeper than that of its parent type. In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

Reason: If the parent is a limited formal type, then the actual might be nonlimited.

Ada 95 required the record extensions to be the same level as the parent type. Now we use accessibility checks on class-wide allocators and return statements to prevent objects from living longer than their type. A similar accessibility rule is not needed for private extensions, because in a package, the rule will apply to the full_type_declaration, and for a generic formal private extension, the actual is all that matters.

Synchronized tagged types cannot be extended. We have this limitation so that all of the data of a task or protected type is defined within the type. Data defined outside of the type wouldn't be subject to the mutual exclusion properties of a protected type, and couldn't be used by a task, and thus doesn't seem to be worth the potential impact on implementations.
Within the body of a generic unit, or the body of any of its descendant library units, a tagged type extension shall not be declared as a descendant of a formal type declared within the formal part of the generic unit in a generic body if the parent type is declared outside that body.

Reason: This paragraph ensures that a dispatching call will never attempt to execute an inaccessible subprogram body.

The convoluted wording (“formal type declared within the formal part”) is necessary to include tagged types that are formal parameters of formal packages of the generic unit, as well as formal tagged and tagged formal derived types of the generic unit.

This rule is necessary in order to preserve the contract model.

If an ancestor is a formal of the generic unit, we have a problem. If the parent is declared in the generic declaration (but is not a formal), we don’t run afoul of the accessibility rules, because we know that the instance declaration and body will be at the same accessibility level. However, we still have a problem in that case, because it might have an unknown number of abstract subprograms that require overriding, as in the following example:

```ada
package P is
  type T is tagged null record;
  function F return T;  -- Inherited versions will require overriding => abstract
end P;

generic
  type TT is tagged private;
package Gp is
  type NT is abstract new TT with null record;
  procedure Q(X : in NT) is abstract;
end Gp;

package body Gp is
  type NT2 is new NT with null record; -- Illegal!
  procedure Q(X : in NT2) is begin null; end Q;
  -- Is this legal or not? Can't decide because
  -- we don't know whether TT had any functions that require => abstract
  -- overriding on extension.
end Gp;

package I is new Gp(TT => P.T);
```

I.NT is an abstract type with two abstract subprograms: F (inherited as abstract) and Q (explicitly declared as abstract). But the generic body doesn’t know about F, so we don’t know that it needs to be overridden to make a nonabstract extension of NT. Furthermore, a formal tagged limited private type can be extended with limited components, but the actual might not be limited, which would allow assignment of limited types, which is bad. Hence, we have to disallow this case as well.

Similarly, since the actual type for a formal tagged limited private type can be a nonlimited type, we would have a problem if a type extension of a limited private formal type could be declared in a generic body. Such an extension could have a task component, for example, and an object of that type could be passed to a dispatching operation of a nonlimited ancestor type. That operation could try to copy the object with the task component. That would be bad. So we disallow this as well.

If TT were declared as abstract, then we could have the same problem with abstract procedures.

We decided not to go that far, in order to avoid unnecessary restrictions.

We also considered trying make the accessibility level part of the contract; i.e. invent some way of saying (in the generic declaration) “all instances of this generic unit will have the same accessibility level as the generic declaration.” Unfortunately, that doesn't solve the part of the problem having to do with abstract types.

This paragraph was deleted. Children of generic units obviate the need for extension in the body somewhat.

Ramification: [AI95-00344] This rule applies to types with ancestors (directly or indirectly) of formal interface types (see 12.5.5), formal tagged private types (see 12.5.1), and formal derived private types whose ancestor type is tagged (see 12.5.1).
Dynamic Semantics

The elaboration of a record_extension_part consists of the elaboration of the record_definition.

NOTES

71 The term “type extension” refers to a type as a whole. The term “extension part” refers to the piece of text that defines the additional components (if any) the type extension has relative to its specified ancestor type.

Discussion: We considered other terminology, such as “extended type.” However, the terms “private extended type” and “record extended type” did not convey the proper meaning. Hence, we have chosen to uniformly use the term “extension” as the type resulting from extending a type, with “private extension” being one produced by privately extending the type, and “record extension” being one produced by extending the type with an additional record-like set of components. Note also that the term “type extension” refers to the result of extending a type in the language Oberon as well (though there the term “extended type” is also used, interchangeably, perhaps because Oberon doesn’t have the concept of a “private extension”).

72 [AI95-00344-01] The accessibility rules imply that a tagged type declared in a library package_specification can be extended only at library level or as a generic formal. When an extension is declared immediately within a body, primitive subprograms are inherited and are overridable, but new primitive subprograms cannot be added.

73 A name that denotes a component (including a discriminant) of the parent type is not allowed within the record_extension_part. Similarly, a name that denotes a component defined within the record_extension_part is not allowed within the record_extension_part. It is permissible to use a name that denotes a discriminant of the record extension, providing there is a new known_discriminant_part in the enclosing type declaration. (The full rule is given in 3.8.)

Reason: The restriction against depending on discriminants of the parent is to simplify the definition of extension aggregates. The restriction against using parent components in other ways is methodological; it presumably simplifies implementation as well.

74 Each visible component of a record extension has to have a unique name, whether the component is (visibly) inherited from the parent type or declared in the record_extension_part (see 8.3).

Examples of record extensions (of types defined above in 3.9):

```ada
type Painted_Point is new Point with
record
  Paint : Color := White;
end record;
-- Components X and Y are inherited

Origin : constant Painted_Point := (X | Y => 0.0, Paint => Black);

type Literal is new Expression with
record
  Value : Real;
-- a leaf in an Expression tree
end record;

type Expr_Ptr is access all Expression'Class;
-- see 3.10

type Binary_Operation is new Expression with
record
  Left, Right : Expr_Ptr;
-- an internal node in an Expression tree
end record;

type Addition is new Binary_Operation with null record;
type Subtraction is new Binary_Operation with null record;
-- No additional components needed for these extensions

Tree : Expr_Ptr :=
new Addition'(
  Left  => new Literal'(Value => 5.0),
  Right => new Subtraction'(
    Left  => new Literal'(Value => 13.0),
    Right => new Literal'(Value => 7.0)));
```

Extensions to Ada 83

Type extension is a new concept.
Extensions to Ada 95

{AI95-00344-01} Type extensions now can be declared in more nested scopes than their parent types. Additional accessibility checks on allocators and return statements prevent objects from outliving their type.

Wording Changes from Ada 95

{AI95-00345-01} Added wording to prevent extending synchronized tagged types.
{AI95-00391-01} Defined null extension for use elsewhere.

3.9.2 Dispatching Operations of Tagged Types

{AI95-00260-02} {AI95-00335-01} The primitive subprograms of a tagged type, the subprograms declared by formal abstract subprogram declarations, and the stream attributes of a specific tagged type that are available (see 13.13.2) at the end of the declaration list where the type is declared are called dispatching operations. [A dispatching operation can be called using a statically determined controlling tag, in which case the body to be executed is determined at compile time. Alternatively, the controlling tag can be dynamically determined, in which case the call dispatches to a body that is determined at run time:] such a call is termed a dispatching call. [As explained below, the properties of the operands and the context of a particular call on a dispatching operation determine how the controlling tag is determined, and hence whether or not the call is a dispatching call. Run-time polymorphism is achieved when a dispatching operation is called by a dispatching call.]

Reason: {AI95-00335-01} For the stream attributes of a type declared immediately within a package specification that has a partial view, the declaration list to consider is the visible part of the package. Stream attributes that are not available in the same declaration list are not dispatching as there is no guarantee that descendants of the type have available attributes (there is such a guarantee for visibly available attributes). If we allowed dispatching for any available attribute, then for attributes defined in the private part we could end up executing a nonexistent body.

Language Design Principles

The controlling tag determination rules are analogous to the overload resolution rules, except they deal with run-time type identification (tags) rather than compile-time type resolution. As with overload resolution, controlling tag determination may depend on operands or result context.

Static Semantics

{AI95-00260-02} {AI95-00416-01} {AI05-0076-1} A call on a dispatching operation is a call whose name or prefix denotes the declaration of a primitive subprogram of a tagged type, that is, a dispatching operation. A controlling operand in a call on a dispatching operation of a tagged type \( T \) is one whose corresponding formal parameter is of type \( T \) or is of an anonymous access type with designated type \( T \); the corresponding formal parameter is called a controlling formal parameter. If the controlling formal parameter is an access parameter, the controlling operand is the object designated by the actual parameter, rather than the actual parameter itself. If the call is to a (primitive) function with result type \( T \) (a function with a controlling result), then the call has a controlling result — the context of the call can control the dispatching. Similarly, if the call is to a function with an access result type designating \( T \) (a function with a controlling access result), then the call has a controlling access result, and the context can similarly control dispatching.

Ramification: This definition implies that a call through the dereference of an access-to-subprogram value is never considered a call on a dispatching operation. Note also that if the prefix denotes a renaming declaration, the place where the renaming occurs determines whether it is primitive; the thing being renamed is irrelevant.

A name or expression of a tagged type is either statically tagged, dynamically tagged, or tag indeterminate, according to whether, when used as a controlling operand, the tag that controls dispatching is determined statically by the operand's (specific) type, dynamically by its tag at run time, or from context. A qualified_expression or parenthesized expression is statically, dynamically, or
indeterminately tagged according to its operand. For other kinds of names and expressions, this is determined as follows:

4/2

• \{AI95-00416-01\} The name or expression is \textit{statically tagged} if it is of a specific tagged type and, if it is a call with a controlling result or controlling access result, it has at least one statically tagged controlling operand;

4.a

\textbf{Discussion:} It is illegal to have both statically tagged and dynamically tagged controlling operands in the same call -- see below.

5/2

• \{AI95-00416-01\} The name or expression is \textit{dynamically tagged} if it is of a class-wide type, or it is a call with a controlling result or controlling access result and at least one dynamically tagged controlling operand;

6/2

• \{AI95-00416-01\} The name or expression is \textit{tag indeterminate} if it is a call with a controlling result or controlling access result, all of whose controlling operands (if any) are tag indeterminate.

7/1

\{8652/0010\} \{AI95-00127-01\} [A \textit{type_conversion} is statically or dynamically tagged according to whether the type determined by the \textit{subtype_mark} is specific or class-wide, respectively.] \textbf{For an object that is designated by an expression whose expected type is an anonymous access-to-specific tagged type, the object is dynamically tagged if the expression, ignoring enclosing parentheses, is of the form \textit{X'Access}, where \textit{X} is of a class-wide type, or is of the form \textit{new \textit{T}'(...)}, where \textit{T} denotes a class-wide subtype. Otherwise, the object is statically tagged if the expression is of an anonymous access-to-specific tagged type, and is dynamically tagged if the object is designated by an actual parameter, the controlling operand is statically or dynamically tagged according to whether the designated type of the \textit{expression} of the actual parameter is specific or class-wide, respectively.}

7.a

\textbf{Ramification:} A \textit{type_conversion} is never tag indeterminate, even if its operand is. A designated object is never tag indeterminate.

7.a.1/1

\{8652/0010\} \{AI95-00127-01\} Allocators and access attributes of class-wide types can be used as the controlling parameters of dispatching calls.

\textit{Legality Rules}

A call on a dispatching operation shall not have both dynamically tagged and statically tagged controlling operands.

8.a

\textbf{Reason:} This restriction is intended to minimize confusion between whether the dynamically tagged operands are implicitly converted to, or tag checked against the specific type of the statically tagged operand(s).

9/1

\{8652/0010\} \{AI95-00127-01\} If the expected type for an expression or name is some specific tagged type, then the expression or name shall not be dynamically tagged unless it is a controlling operand in a call on a dispatching operation. Similarly, if the expected type for an expression is an anonymous access-to-specific tagged type, then the \textit{object designated by the expression shall not be dynamically tagged unless it is an expression} shall not be of an access-to-class-wide type unless it designates a controlling operand in a call on a dispatching operation.

9.a

\textbf{Reason:} This prevents implicit "truncation" of a dynamically-tagged value to the specific type of the target object/formal. An explicit conversion is required to request this truncation.

9.b/2

\textbf{Ramification:} \{AI95-00252-01\} This rule applies to all expressions or names with a specific expected type, not just those that are actual parameters to a dispatching call. This rule does not apply to a membership test whose expression is class-wide, since any type that covers the tested type is explicitly allowed. See 4.5.2. \textbf{This rule also doesn't apply to a \textit{selected_component} whose \textit{selector_name} is a subprogram, since the rules explicitly say that the prefix may be class-wide (see 4.1.3.).}

10/2

\{8652/0011\} \{AI95-00117-01\} \{AI95-00430-01\} In the declaration of a dispatching operation of a tagged type, everywhere a subtype of the tagged type appears as a subtype of the profile (see 6.1), it shall statically match the first subtype of the tagged type. If the dispatching operation overrides an inherited subprogram, it shall be subtype conformant with the inherited subprogram. \textbf{The convention of an inherited or overriding dispatching operation is the convention of the corresponding primitive operation of the parent or progenitor type. The default convention of a dispatching operation that overrides another}
inherited primitive operation is the convention of the inherited operation; if the operation overrides multiple inherited operations, then they shall all have the same convention. An explicitly declared dispatching operation shall not be of convention Intrinsic. If a dispatching operation overrides the predefined equals operator, then it shall be of convention Ada {{either explicitly or by default—see 6.3.1}}.

**Reason:** These rules ensure that constraint checks can be performed by the caller in a dispatching call, and parameter passing conventions match up properly. A special rule on aggregates prevents values of a tagged type from being created that are outside of its first subtype.

{AI95-00416-01} The default_expression for a controlling formal parameter of a dispatching operation shall be tag indeterminate. A controlling formal parameter that is an access parameter shall not have a default_expression.

**Reason:** {AI95-00416-01} This rule ensures that the default_expression always produces the "correct" tag when called with or without dispatching, or when inherited by a descendant. If it were statically tagged, the default would be useless for a dispatching call; if it were dynamically tagged, the default would be useless for a nondispatching call.

{AI95-00416-01} The second part is consistent with the first part, since designated objects are never tag indeterminate.

{AI95-00404-01} If a dispatching operation is defined by a subprogram_renaming_declaration or the instantiation of a generic subprogram, any access parameter of the renamed subprogram or the generic subprogram that corresponds to a controlling access parameter of the dispatching operation, shall have a subtype that excludes null.

A given subprogram shall not be a dispatching operation of two or more distinct tagged types.

**Reason:** This restriction minimizes confusion since multiple dispatching is not provided. The normal solution is to replace all but one of the tagged types with their class-wide types.

**Ramification:** {8652/0098} {AI95-00183-01} This restriction applies even if the partial view (see 7.3) of one or both of the types is untagged. This follows from the definition of dispatching operation: the operation is a dispatching operation anywhere the full views of the (tagged) types are visible.

The explicit declaration of a primitive subprogram of a tagged type shall occur before the type is frozen (see 13.14). [For example, new dispatching operations cannot be added after objects or values of the type exist, nor after deriving a record extension from it, nor after a body.]

**Reason:** {AI95-00344-01} This rule is needed because (1) we don't want people dispatching to things that haven't been declared yet, and (2) we want to allow the static part of tagged type descriptors to be static (allocated statically, and initialized to link-time-known symbols). Suppose T2 inherits primitive P from T1, and then overrides P. Suppose P is called before the declaration of the overriding P. What should it dispatch to? If the answer is the new P, we've violated the first principle above. If the answer is the old P, we've violated the second principle. (A call to the new one necessarily raises Program_Error, but that's beside the point.)

Note that a call upon a dispatching operation of type T will freeze T.

We considered applying this rule to all derived types, for uniformity. However, that would be upward incompatible, so we rejected the idea. As in Ada 83, for an untagged type, the above call upon P will call the old P (which is arguably confusing).

**Implementation Note:** {AI95-00326-01} Because of this rule, the type descriptor can be created (presumably containing linker symbols pointing at the not-yet-compiled bodies) at the first freezing point of the type. It also prevents, for a {nonincomplete} tagged type declared in a package_specification, overriding in the body or by a child subprogram.

**Ramification:** {AI95-00251-01} A consequence is that for a tagged type declaration derived_type_declaration in a declarative_part, only the last (overriding) first primitive subprogram can be declared by a subprogram_body. Other overwhelments must be provided by subprogram_declarations.

**To be honest:** {AI05-0222-1} This rule applies only to "original" declarations and not to the completion of a primitive subprogram, even though a completion is technically an explicit declaration, and it may declare a primitive subprogram.
For the execution of a call on a dispatching operation of a type \( T \), the \textit{controlling tag value} determines which subprogram body is executed. The controlling tag value is defined as follows:

- If one or more controlling operands are statically tagged, then the controlling tag value is \textit{statically determined} to be the tag of \( T \).

- If one or more controlling operands are dynamically tagged, then the controlling tag value is not statically determined, but is rather determined by the tags of the controlling operands. If there is more than one dynamically tagged controlling operand, a check is made that they all have the same tag. If this check fails, \texttt{Constraint_Error} is raised unless the call is a function call whose \texttt{name} denotes the declaration of an equality operator (predefined or user defined) that returns \texttt{Boolean}, in which case the result of the call is defined to indicate inequality, and no \texttt{subprogram_body} is executed. This check is performed prior to evaluating any tag-indeterminate controlling operands.

\textbf{Reason:} Tag mismatch is considered an error (except for "\texttt{=}" and "\texttt{/=}") since the corresponding primitive subprograms in each specific type expect all controlling operands to be of the same type. For tag mismatch with an equality operator, rather than raising an exception, "\texttt{=}" returns \texttt{False} and "\texttt{/=}" returns \texttt{True}. No equality operator is actually invoked, since there is no common tag value to control the dispatch. Equality is a special case to be consistent with the existing Ada 83 principle that equality comparisons, even between objects with different constraints, never raise \texttt{Constraint_Error}.

- {\textit{AI95-00196-01}} If all of the controlling operands (if any) are tag-indeterminate, then:

  - \{\textit{AI95-00239-01}\} \{\textit{AI95-00416-01}\} If the call has a controlling result or controlling access result and is itself, or designates, a (possibly parenthesized or qualified) controlling operand of an enclosing call on a dispatching operation of a \textit{descendant of} type \( T \), then its controlling tag value is determined by the controlling tag value of this enclosing call;

\textbf{Discussion:} \{\textit{AI95-00239-01}\} For code that a user can write explicitly, the only contexts that can control dispatching of a function with a controlling result of type \( T \) are those that involve controlling operands of the same type \( T \): if the two types differ there is an illegality and the dynamic semantics are irrelevant.

In the case of an inherited subprogram however, if a default expression is a function call, it may be of type \( T \) while the parameter is of a type derived from \( T \). To cover this case, we talk about "a descendant of \( T \)" above. This is safe, because if the type of the parameter is descended from the type of the function result, it is guaranteed to inherit or override the function, and this ensures that there will be an appropriate body to dispatch to. Note that abstract functions are not an issue here because the call to the function is a dispatching call, so it is guaranteed to always land on a concrete body.

- {\textit{AI95-00196-01}} If the call has a controlling result or controlling access result and (possibly parenthesized, qualified, or dereferenced) is the expression of an \texttt{assignment_statement} whose target is of a class-wide type, then its controlling tag value is determined by the target;

- Otherwise, the controlling tag value is statically determined to be the tag of type \( T \).

\textbf{Ramification:} This includes the cases of a tag-indeterminate procedure call, and a tag-indeterminate function call that is used to initialize a class-wide formal parameter or class-wide object.

{\textit{AI95-00345-01}} \{\textit{AI05-0126-1}\} For the execution of a call on a dispatching operation, the \textit{action} performed is determined by the properties of the corresponding dispatching operation body executed is the one for the corresponding \texttt{primitive subprogram} of the specific type identified by the controlling tag value. If the corresponding operation is implicitly declared for this type, then the action comprises an invocation of the dispatching operation body of the \texttt{operation}. If the corresponding operation is explicitly declared for this \texttt{subprogram}, the body for an implicitly declared dispatching operation that is overridden is the body for the \texttt{overriding subprogram}. If the \texttt{overriding operation occurs in a private part}, the body for an \textit{inherited dispatching operation} that is not \texttt{overridden} is the body for the corresponding \texttt{subprogram} of the \texttt{parent or ancestor type}.
• \{AI05-0126-1\} if the corresponding operation is explicitly declared for this type, [even if the declaration occurs in a private part], then the action comprises an invocation of the explicit body for the operation;

• \{AI95-00345-01\} \{AI05-0126-1\} if the corresponding operation is implicitly declared for this type and is implemented by an entry or protected subprogram (see 9.1 and 9.4), then the action comprises a call on this entry or protected subprogram, with the target object being given by the first actual parameter of the call, and the actual parameters of the entry or protected subprogram being given by the remaining actual parameters of the call, if any;

• \{AI05-0197-1\} if the corresponding operation is a predefined operator then the action comprises an invocation of that operator;

• \{AI95-00345-01\} \{AI05-0126-1\} \{AI05-0197-1\} \{AI05-0250-1\} \{AI05-0254-1\} otherwise, the action is the same as the action for the corresponding operation of the parent type or progenitor type from which the operation was inherited except that additional invariant checks (see 7.3.2) and class-wide postcondition checks (see 6.1.1) may apply. If there is more than one such corresponding operation, the action is that for the operation that is not a null procedure, if any; otherwise, the action is that of an arbitrary one of the operations.

This paragraph was deleted. To be honest: \{AI05-0126-1\} In the unusual case in which a dispatching subprogram is explicitly declared (overridden) by a body (with no preceding subprogram_declaration), the body for that dispatching subprogram is that body; that is, the “corresponding explicit body” in the above rule is the body itself.

Ramification: \{AI05-0005-1\} \{AI05-0126-1\} “Corresponding dispatching operation” refers to the inheritance relationship between subprograms. Primitive operations are always inherited for a type T, but they might not be declared if the primitive operation is never visible within the immediate scope of the type T. If no corresponding operation is declared, the last bullet is used and the corresponding operation of the parent type is executed (an explicit body that happens to have the same name and profile is not called in that case).

\{AI05-0005-1\} \{AI05-0126-1\} We have to talk about progenitors in the last bullet in case the corresponding operation is a null procedure inherited from an interface. In that case, the parent type might not even have the operation in question.

\{AI05-0197-1\} For the last bullet, if there are multiple corresponding operations for the parent and progenitors, all but one of them have to be a null procedure. (If the progenitors declared abstract routines, there would have to be an explicit overriding of the operation, and then the first bullet would apply.) We call the nonnull routine if one exists.

\{AI05-0126-1\} Any explicit declaration for an inherited corresponding operation has to be an overriding routine. These rules mean that a dispatching call executes the overriding routine (if any) for the specific type.

Reason: \{AI05-0005-1\} The wording of the above rules is intended to ensure that the same body is executed for a given tag, whether that tag is determined statically or dynamically. For a type declared in a package, it doesn't matter whether a given subprogram is overridden in the visible part or the private part, and it doesn't matter whether the call is inside or outside the package. For example:

```ada
package P1 is
  type T1 is tagged null record;
  procedure Op_A(Arg : in T1);
  procedure Op_B(Arg : in T1);
end P1;

with P1; use P1;

package P2 is
  type T2 is new T1 with null record;
  procedure Op_A(Param : in T2);
private
  procedure Op_B(Param : in T2);
end P2;

with P1; with P2;

procedure Main is
  X : P2.T2;
  Y : P1.T1'Class := X;
begin
  P2.Op_A(Param => X); -- Nondispatching call to a dispatching operation.
  P1.Op_A(Arg => Y); -- Dispatching call.
  P2.Op_B(Param => X); -- Nondispatching call to a dispatching operation.
  P1.Op_B(Arg => Y); -- Dispatching call.
end Main;
```
The two calls to Op_A both execute the body of Op_A that has to occur in the body of package P2. Similarly, the two calls to Op_B both execute the body of Op_B that has to occur in the body of package P2, even though Op_B is overridden in the private part of P2. Note, however, that the formal parameter names are different for P2.Op_A versus P2.Op_B. The overriding declaration for P2.Op_B is not visible in Main, so the name in the call actually denotes the implicit declaration of Op_B inherited from T1.

If a call occurs in the program text before an overriding, which can happen only if the call is part of a default expression, the overriding will still take effect for that call.

Implementation Note: Even when a tag is not statically determined, a compiler might still be able to figure it out and thereby avoid the overhead of run-time dispatching.

NOTES
75 The body to be executed for a call on a dispatching operation is determined by the tag; it does not matter whether that tag is determined statically or dynamically, and it does not matter whether the subprogram's declaration is visible at the place of the call.

76 \{AI95-00260-02\} This subclause covers calls on dispatching primitive subprograms of a tagged type. Rules for tagged type membership tests are described in 4.5.2. Controlling tag determination for an assignment_statement is described in 5.2.

77 A dispatching call can dispatch to a body whose declaration is not visible at the place of the call.

78 A call through an access-to-subprogram value is never a dispatching call, even if the access value designates a dispatching operation. Similarly a call whose prefix denotes a subprogram_renaming_declaration cannot be a dispatching call unless the renaming itself is the declaration of a primitive subprogram.

Extensions to Ada 83

The concept of dispatching operations is new.

Incompatibilities With Ada 95

\{AI95-00404-01\} If a dispatching operation is defined by a subprogram_renaming_declaration, and it has a controlling access parameter, Ada 2005 requires the subtype of the parameter to exclude null. The same applies to instantiations. This is required so that all calls to the subprogram operate the same way (controlling access parameters have to exclude null so that dispatching calls will work). Since Ada 95 didn't have the notion of access subtypes that exclude null, and all access parameters excluded null, it had no such rules. These rules will require the addition of an explicit not null on nondispatching operations that are later renamed to be dispatching, or on a generic that is used to define a dispatching operation.

Extensions to Ada 95

\{AI95-00416-01\} Functions that have an access result type can be dispatching in the same way as a function that returns a tagged object directly.

Wording Changes from Ada 95

\{8652/0010\} \{AI95-00127-01\} \{AI05-0299-1\} Corrigendum: Allocators and access attributes of objects of class-wide types can be used as the controlling parameter in a dispatching calls. This was an oversight in the definition of Ada 95. (See 3.10.2 and 4.8).

\{8652/0011\} \{AI95-00117-01\} \{AI95-00430-01\} Corrigendum: Corrected the conventions of dispatching operations. This is extended in Ada 2005 to cover operations inherited from progenitors, and to ensure that the conventions of all inherited operations are the same.

\{AI95-00019-01\} Clarified the wording to ensure that functions with no controlling operands are tag-indeterminate, and to describe that the controlling tag can come from the target of an assignment_statement.

\{AI95-00239-01\} Fixed the wording to cover default expressions inherited by derived subprograms. A literal reading of the old wording would have implied that operations would be called with objects of the wrong type.

\{AI95-00260-02\} An abstract formal subprogram is a dispatching operation, even though it is not a primitive operation. See 12.6, “Formal Subprograms”.

\{AI95-00345-01\} Dispatching calls include operations implemented by entries and protected operations, so we have to update the wording to reflect that.

\{AI95-00335-01\} A stream attribute of a tagged type is usually a dispatching operation, even though it is not a primitive operation. If they weren't dispatching, TClass'Input and TClass'Output wouldn't work.
3.9.3 Abstract Types and Subprograms

An abstract type is a tagged type intended for use as an ancestor of other types, but which is not allowed to have objects of its own. An abstract subprogram is a subprogram that has no body, but is intended to be overridden at some point when inherited. Because objects of an abstract type cannot be created, a dispatching call to an abstract subprogram always dispatches to some overriding body.

Glossary entry: An abstract type is a tagged type intended for use as an ancestor of other types, but which is not allowed to have objects of its own.

Language Design Principles

An abstract subprogram has no body, so the rules in this subclause are designed to ensure (at compile time) that the body will never be invoked. We do so primarily by disallowing the creation of values of the abstract type. Therefore, since type conversion and parameter passing don't change the tag, we know we will never get a class-wide value with a tag identifying an abstract type. This means that we only have to disallow nondispatching calls on abstract subprograms (dispatching calls will never reach them).

Syntax

abstract_subprogram_declaration ::= [overriding_indicator] subprogram_specification is abstract [aspect_specification];

Static Semantics

Interface types (see 3.9.4) are abstract types. In addition, a tagged type that has the reserved word abstract in its declaration is an abstract type. The class-wide type (see 3.4.1) rooted at an abstract type is not itself an abstract type.

Legality Rules

Only a tagged type shall have abstract in its declaration. Only a tagged type is allowed to be declared abstract.

Ramification: Untagged types are never abstract, even though they can have primitive abstract subprograms. Such subprograms cannot be called, unless they also happen to be dispatching operations of some tagged type, and then only via a dispatching call.

Class-wide types are never abstract. If T is abstract, then it is illegal to declare a stand-alone object of type T, but it is OK to declare a stand-alone object of type T'Class; the latter will get a tag from its initial value, and this tag will necessarily be different from T'Tag.

A subprogram declared by an abstract_subprogram_declaration or a formal_abstract_subprogram_declaration (see 12.6) is an abstract subprogram. If it is a primitive subprogram of a tagged type, then the tagged type shall be abstract.

Ramification: Note that for a private type, this applies to both views. The following is illegal:

```ada
package P is
  type T is abstract tagged private;
  function Foo (X : T) return Boolean is abstract; -- Illegal!
private
  type T is tagged null record; -- Illegal!
  X : T;
  Y : Boolean := Foo (T'Class (X));
end P;
```
The full view of T is not abstract, but has an abstract operation Foo, which is illegal. The two lines marked "-- Illegal!" are illegal when taken together.

**Reason:** \{AI95-00310-01\} We considered disallowing untagged types from having abstract primitive subprograms. However, we rejected that plan, because it introduced some silly anomalies, and because such subprograms are harmless (if not terribly useful). For example:

```ada
package P is
    type Field_Size is range 0..100;
    type T is abstract tagged null record;
    procedure Print(X : in T; F : in Field_Size := 0) is abstract;
end P;
```

```ada
package Q is
    type My_Field_Size is new Field_Size;
    -- implicit declaration of Print(X : T; F : My_Field_Size := 0) is abstract;
end Q;
```

It seemed silly to make the derivative of My_Field_Size illegal, just because there was an implicitly declared abstract subprogram that was not primitive on some tagged type. Other rules could be formulated to solve this problem, but the current ones seem like the simplest.

**Ramification:** \{AI95-00310-01\} In Ada 2005, abstract primitive subprograms of an untagged type may be used to “undefine” an operation.

**Ramification:** \{AI95-00260-02\} Note that the second sentence does not apply to abstract formal subprograms, as they are never primitive operations of a type.

**Ramification:** \{AI95-00251-01\} \{AI95-00334-01\} \{AI95-00391-01\} \{AI05-0097-1\} \{AI05-0198-1\} If a type has an implicitly declared primitive subprogram that is inherited or is the predefined equality operator, and the corresponding primitive subprogram of a derived type is abstract or is a function with a controlling access result, or if a type other than a nonabstract null extension inherits a function with a controlling result, then:

```ada
package P is
    type I is interface;
    procedure Op (X : I) is abstract;
end P;
```

```ada
with P;
package Q is
    type T is abstract new P.I with private;
    -- Op inherited here.
    private
        type T is abstract new P.I with null record;
        procedure Op (X : T) is null;
    end Q;
end Q;
```

```ada
with Q;
package R is
    type T2 is new Q.T with null record;
    -- Illegal. Op inherited here, but requires overriding.
end R;
```

If this did not depend on the view, this would be legal. But in that case, the fact that Op is overridden in the private part would be visible; package R would have to be illegal if no overriding was in the private part.

Note that this means that whether an inherited subprogram is abstract or concrete depends on where it inherited. In the case of Q.Q.Op in the visible part is abstract, while Q.Q.Op in the private part is concrete. That is, R is illegal since it is an unrelated unit (and thus it cannot see the private part), but if R had been a private child of Q, it would have been legal.

- \{AI95-00251-01\} \{AI95-00334-01\} If the derived-type is abstract or untagged, the implicitly declared inherited subprogram is abstract.

**Ramification:** Note that it is possible to override a concrete subprogram with an abstract one.

- \{AI95-00391-01\} Otherwise, the subprogram shall be overridden with a nonabstract subprogram or, in the case of a private extension inheriting a function with a controlling result, have a full type that is a null extension; for a type declared in the visible part of a package, the overriding may be either in the visible or the private part. Such a subprogram is said to require overriding.
However, if the type is a generic formal type, the subprogram need not be overridden for the formal type itself; [a nonabstract version will necessarily be provided by the actual type.]

**Reason:** [A195-00228-01] [A195-00391-01] A function that returns the parent type requires overriding becomes abstract for an abstract type extension (or becomes abstract for an abstract type if not overridden) because conversion from a parent type to a type extension is not defined, and function return semantics is defined in terms of conversion (other than for a null extension; see below). (Note that parameters of mode in or out do not have this problem, because the tag of the actual is not changed.)

Note that the overriding required above can be in the private part, which allows the following:

```ada
package Pack1 is
  type Ancestor is abstract ...;
  procedure Do_Something(X : in Ancestor) is abstract;
end Pack1;
with Pack1; use Pack1;
package Pack2 is
  type T1 is new Ancestor with record ...;
  procedure Do_Something(X : in T1); -- Have to override.
end Pack2;
with Pack1; use Pack1;
with Pack2; use Pack2;
package Pack3 is
  type T2 is new Ancestor with private;
  -- A concrete type.
  procedure Do_Something(X : in T2); -- Here, we inherit Pack2.Do_Something.
end Pack3;
```

{T2} inherits an abstract Do_Something, but T2 is not abstract, so Do_Something has to be overridden. However, it is OK to override it in the private part. In this case, we override it by inheriting a concrete version from a different type. Nondispatching calls to Pack3.Do_Something are allowed both inside and outside package Pack3, as the client "knows" that the subprogram was necessarily overridden somewhere.

**Reason:** [A195-00391-01] For a null extension, the result of a function with a controlling result is defined in terms of an extension_aggregate with a null record extension part (see 3.4). This means that these restrictions on functions with a controlling result do not have to apply to null extensions.

{T2} However, functions with controlling access results still require overriding. Changing the tag in place might clobber a preexisting object, and allocating new memory would possibly change the pool of the object, leading to storage leaks. Moreover, copying the object isn't possible for limited types. We don't need to restrict functions that have an access return type of an untagged type, as derived types with primitive subprograms have to have the same representation as their parent type.

A call on an abstract subprogram shall be a dispatching call; [nondispatching calls to an abstract subprogram are not allowed.]

**Ramification:** [A195-00310-01] If an abstract subprogram is not a dispatching operation of some tagged type, then it cannot be called at all. In Ada 2005, such subprograms are not even considered by name resolution (see 6.4).

The type of an aggregate, or of an object created by an object_declaration or an allocator, or a generic formal object of mode in, shall not be abstract. The type of the target of an assignment operation (see 5.2) shall not be abstract. The type of a component shall not be abstract. If the result type of a function is abstract, then the function shall be abstract. If a function has an access result type designating an abstract type, then the function shall be abstract. The type denoted by a return_subtype_indication (see 6.5) shall not be abstract. A generic function shall not have an abstract result type or an access result type designating an abstract type.

**Reason:** This ensures that values of an abstract type cannot be created, which ensures that a dispatching call to an abstract subprogram will not try to execute the nonexistent body.

Generic formal objects of mode in are like constants; therefore they should be forbidden for abstract types. Generic formal objects of mode in out are like renamings; therefore, abstract types are OK for them, though probably not terribly useful.
3.9.3 Abstract Types and Subprograms 13 December 2012 144

Generic functions returning a formal abstract type are illegal because any instance would have to be instantiated with a nonabstract type in order to avoid violating the function rule (generic functions cannot be declared abstract). But that would be an implied contract; it would be better for the contract to be explicit by the formal type not being declared abstract. Moreover, the implied contract does not add any capability.

If a partial view is not abstract, the corresponding full view shall not be abstract. If a generic formal type is abstract, then for each primitive subprogram of the formal that is not abstract, the corresponding primitive subprogram of the actual shall not be abstract.

Discussion: By contrast, we allow the actual type to be nonabstract even if the formal type is declared abstract. Hence, the most general formal tagged type possible is "type T(<>) is abstract tagged limited private;".

For an abstract private extension declared in the visible part of a package, it is only possible for the full type to be nonabstract if the private extension has no abstract dispatching operations.

To be honest: {AI95-00294-01} In the sentence about primitive subprograms above, there is some ambiguity as to what is meant by "corresponding" in the case where an inherited operation is overridden. This is best explained by an example, where the implicit declarations are shown as comments:

```
package P1 is
  type T1 is abstract tagged null record;
  procedure P (X : T1); -- (1)
end P1;

package P2 is
  type T2 is abstract new P1.T1 with null record;
  -- procedure P (X : T2); -- (2)
  procedure P (X : T2) is abstract; -- (3)
end P2;

generic type D is abstract new P1.T1 with private;
  -- procedure P (X : D); -- (4)
procedure G (X : D);
procedure I is new G (P2.T2); -- Illegal.
```

Type T2 inherits a nonabstract procedure P (2) from the primitive procedure P (1) of T1. P (2) is overridden by the explicitly declared abstract procedure P (3). Type D inherits a nonabstract procedure P (4) from P (1). In instantiation I, the operation corresponding to P (4) is the one which is not overridden, that is, P (3): the overridden operation P (2) does not "reemerge". Therefore, the instantiation is illegal.

For an abstract type declared in a visible part, an abstract primitive subprogram shall not be declared in the private part, unless it is overriding an abstract subprogram implicitly declared in the visible part. For a tagged type declared in a visible part, a primitive function with a controlling result or a controlling access result shall not be declared in the private part, unless it is overriding a function implicitly declared in the visible part.

Reason: The "visible part" could be that of a package or a generic package. This rule is needed because a nonabstract type extension declared outside the package would not know about any abstract primitive subprograms or primitive functions with controlling results declared in the private part, and wouldn't know that they need to be overridden with nonabstract subprograms. The rule applies to a tagged record type or record extension declared in a visible part, just as to a tagged private type or private extension. The rule applies to explicitly and implicitly declared abstract subprograms:

```
package Pack is
  type T is abstract new T1 with private;
  private
    type T is abstract new T2 with record ... end record;
  end T;
end Pack;
```

The above example would be illegal if T1 has a nonabstract primitive procedure P, but T2 overrides P with an abstract one; the private part should override P with a nonabstract version. On the other hand, if the P were abstract for both T1 and T2, the example would be legal as is.

A generic actual subprogram shall not be an abstract subprogram unless the generic formal subprogram is declared by a formal abstract subprogram declaration. The prefix of an attribute_reference for the Access, Unchecked_Access, or Address attributes shall not denote an abstract subprogram.
Ramification: An abstract subprogram declaration is not syntactically a subprogram declaration. Nonetheless, an abstract subprogram is a subprogram, and an abstract subprogram declaration is a declaration of a subprogram.\footnote{AI95-00260-02} The part about generic actual subprograms includes those given by default. Of course, an abstract formal subprogram’s actual subprogram can be abstract.

Dynamic Semantics

\footnote{AI95-00348-01} The elaboration of an abstract subprogram declaration has no effect.

NOTES

79 Abstractness is not inherited; to declare an abstract type, the reserved word \texttt{abstract} has to be used in the declaration of the type extension.

Ramification: A derived type can be abstract even if its parent is not. Similarly, an inherited concrete subprogram can be overridden with an abstract subprogram.

80 A class-wide type is never abstract. Even if a class is rooted at an abstract type, the class-wide type for the class is not abstract, and an object of the class-wide type can be created; the tag of such an object will identify some nonabstract type in the class.

Examples

Example of an abstract type representing a set of natural numbers:

\begin{verbatim}
package Sets is
  subtype Element_Type is Natural;
  type Set is abstract tagged null record
    Empty : return Set is abstract;
    Union(Left, Right : Set) return Set is abstract;
    Intersection(Left, Right : Set) return Set is abstract;
    Unit_Set(Element : Element_Type) return Set is abstract;
    Take(Element : out Element_Type;
           From : in out Set) is abstract;
  end Sets;
\end{verbatim}

NOTES

81 Notes on the example: Given the above abstract type, one could then derive various (nonabstract) extensions of the type, representing alternative implementations of a set. One might use a bit vector, but impose an upper bound on the largest element representable, while another might use a hash table, trading off space for flexibility.

Discussion: One way to export a type from a package with some components visible and some components private is as follows:

\begin{verbatim}
package P is
  type Public_Part is abstract tagged record
    ... end record;
  type T is new Public_Part with private;
  ... private
    type T is new Public_Part with record
      ... end record;
  end P;
\end{verbatim}

The fact that Public_Part is abstract tells clients they have to create objects of type T instead of Public_Part. Note that the public part has to come first; it would be illegal to declare a private type Private_Part, and then a record extension T of it, unless T were in the private part after the full declaration of Private_Part, but then clients of the package would not have visibility to T.

Extensions to Ada 95

\footnote{AI95-00391-01} It is not necessary to override functions with a controlling result for a null extension. This makes it easier to derive a tagged type to complete a private type.

Wording Changes from Ada 95

\footnote{AI95-00251-01} \footnote{AI95-00345-01} Updated the wording to reflect the addition of interface types (see 3.9.4).

\footnote{AI95-00260-02} Updated the wording to reflect the addition of abstract formal subprograms (see 12.6).
3.9.3 Abstract Types and Subprograms

3.9.4 Interface Types

1.1 [An interface type is an abstract tagged type that provides a restricted form of multiple inheritance. A tagged type, task type, or protected type may have one or more interface types as ancestors.]

Glossary entry: An interface type is a form of abstract tagged type which has no components or concrete operations except possibly null procedures. Interface types are used for composing other interfaces and tagged types and thereby provide multiple inheritance. Only an interface type can be used as a progenitor of another type.

1.2 The rules are designed so that an interface can be used as either a parent type or a progenitor type without changing the meaning. That's important so that the order that interfaces are specified in a derived type definition is not significant. In particular, we want:

```ada
type Con1 is new Int1 and Int2 with null record;
```

```ada
type Con2 is new Int2 and Int1 with null record;
```

to mean exactly the same thing.

Syntax

2.1 \{AI95-00251-01\} \{AI95-00345-01\} interface_type_definition ::= 

[limited | task | protected | synchronized] interface [and interface_list]

3.1 \{AI95-00251-01\} \{AI95-00419-01\} interface_list ::= 

interface_subtype_mark [and interface_subtype_mark]

Static Semantics

4.1 \{AI95-00251-01\} An interface type (also called an interface) is a specific abstract tagged type that is defined by an interface_type_definition.

5.1 \{AI95-00345-01\} An interface with the reserved word limited, task, protected, or synchronized in its definition is termed, respectively, a limited interface, a task interface, a protected interface, or a
synchronized interface. In addition, all task and protected interfaces are synchronized interfaces, and all synchronized interfaces are limited interfaces.

Glossary entry: A synchronized entity is one that will work safely with multiple tasks at one time. A synchronized interface can be an ancestor of a task or a protected type. Such a task or protected type is called a synchronized tagged type.

\{AI95-00345-01\} \{AI95-00443-01\} [A task or protected type derived from an interface is a tagged type.] Such a tagged type is called a synchronized tagged type, as are synchronized interfaces and private extensions whose declaration includes the reserved word synchronized.

Proof: The full definition of tagged types given in 3.9 includes task and protected types derived from interfaces.

Ramification: The class-wide type associated with a tagged task type (including a task interface type) is a task type, because “task” is one of the language-defined classes of types (see 3.2). However, the class-wide type associated with an interface is not an interface type, as “interface” is not one of the language-defined classes (as it is not closed under derivation). In this sense, “interface” is similar to “abstract”. The class-wide type associated with an interface is a concrete (nonabstract) indefinite tagged composite type.

“Private extension” includes generic formal private extensions, as explained in 12.5.1.

\{AI95-00345-01\} A task interface is an [abstract] task type. A protected interface is an [abstract] protected type.

Proof: The “abstract” follows from the definition of an interface type.

Reason: This ensures that task operations (like abort and the Terminated attribute) can be applied to a task interface type and the associated class-wide type. While there are no protected type operations, we apply the same rule to protected interfaces for consistency.

\{AI95-00251-01\} [An interface type has no components.]

Proof: This follows from the syntax and the fact that discriminants are not allowed for interface types.

\{AI95-00419-01\} An interface subtype mark in an interface list names a progenitor subtype; its type is the progenitor type. An interface type inherits user-defined primitive subprograms from each progenitor type in the same way that a derived type inherits user-defined primitive subprograms from its progenitor types (see 3.4).

Glossary entry: A progenitor of a derived type is one of the types given in the definition of the derived type other than the first. A progenitor is always an interface type. Interfaces, tasks, and protected types may also have progenitors.

Legality Rules

\{AI95-00251-01\} All user-defined primitive subprograms of an interface type shall be abstract subprograms or null procedures.

\{AI95-00251-01\} The type of a subtype named in an interface list shall be an interface type.

\{AI95-00251-01\} \{AI95-00345-01\} A type derived from a nonlimited interface shall be nonlimited.

\{AI95-00345-01\} An interface derived from a task interface shall include the reserved word task in its definition; any other type derived from a task interface shall be a private extension or a task type declared by a task declaration (see 9.1).

\{AI95-00345-01\} An interface derived from a protected interface shall include the reserved word protected in its definition; any other type derived from a protected interface shall be a private extension or a protected type declared by a protected declaration (see 9.4).

\{AI95-00345-01\} An interface derived from a synchronized interface shall include one of the reserved words task, protected, or synchronized in its definition; any other type derived from a synchronized interface shall be a private extension, a task type declared by a task declaration, or a protected type declared by a protected declaration.
Reason: We require that an interface descendant of a task, protected, or synchronized interface repeat the explicit kind of interface it will be, rather than simply inheriting it, so that a reader is always aware of whether the interface provides synchronization and whether it may be implemented only by a task or protected type. The only place where inheritance of the kind of interface might be useful would be in a generic if you didn't know the kind of the actual interface. However, the value of that is low because you cannot implement an interface properly if you don't know whether it is a task, protected, or synchronized interface. Hence, we require the kind of the actual interface to match the kind of the formal interface (see 12.5.5).

{AI95-00345-01} No type shall be derived from both a task interface and a protected interface.

Reason: This prevents a single private extension from inheriting from both a task and a protected interface. For a private type, there can be no legal completion. For a generic formal derived type, there can be no possible matching type (so no instantiation could be legal). This rule provides early detection of the errors.

{AI95-00251-01} In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

Ramification: {AI05-0299-I} This paragraph is intended to apply to all of the Legality Rules in this subclause. We cannot allow interface types which do not obey these rules, anywhere. Luckily, deriving from a formal type (which might be an interface) is not allowed for any tagged types in a generic body. So checking in the private part of a generic covers all of the cases.

Dynamic Semantics

{AI95-00251-01} {AI05-0070-1} The elaboration of an interface type definition creates the interface type and its first subtype has no effect.

Discussion: There is no other effect. An interface list is made up of subtype marks, which do not need to be elaborated, so the interface list does not either. This is consistent with the handling of discriminant parts.

NOTES

82 {AI95-00411-01} Nonlimited interface types have predefined nonabstract equality operators. These may be overridden with user-defined abstract equality operators. Such operators will then require an explicit overriding for any nonabstract descendant of the interface.

Examples

{AI95-00433-01} Example of a limited interface and a synchronized interface extending it:

```ada
type Queue is limited interface;
procedure Append(Q : in out Queue; Person : in Person_Name) is abstract;
procedure Remove_First(Q : in out Queue; Person : out Person_Name) is abstract;
function Cur_Count(Q : in Queue) return Natural is abstract;
function Max_Count(Q : in Queue) return Natural is abstract;
-- See 3.10.1 for Person_Name.

{AI05-0004-I} Queue_Error : exception;
-- Append raises Queue_Error if Cur_Count(Q) = Max_Count(Q)
-- Remove First raises Queue_Error if Cur_Count(Q) = 0

type Synchronized_Queue is synchronized interface and Queue; -- see 9.11
procedure Append_Wait(Q : in out Synchronized_Queue; Person : in Person_Name) is abstract;
procedure Remove_First_Wait(Q : in out Synchronized_Queue; Person : out Person_Name) is abstract;

...;
```

```ada
procedure Transfer(From : in out Queue'Class; To : in out Queue'Class; Number : in Natural := 1) is
    Person : Person_Name;
begin
    for I in 1..Number loop
        Append(To, Person);
        Append_Wait(From, Person);
    end loop;
end Transfer;
```
This defines a Queue interface defining a queue of people. (A similar design could be created to define any kind of queue simply by replacing Person_Name by an appropriate type.) The Queue interface has four dispatching operations, Append, Remove_First, Cur_Count, and Max_Count. The body of a class-wide operation, Transfer is also shown. Every nonabstract extension of Queue must provide implementations for at least its four dispatching operations, as they are abstract. Any object of a type derived from Queue may be passed to Transfer as either the From or the To operand. The two operands need not be of the same type in any given call.

The Synchronized Queue interface inherits the four dispatching operations from Queue and adds two additional dispatching operations, which wait if necessary rather than raising the Queue_Error exception. This synchronized interface may only be implemented by a task or protected type, and as such ensures safe concurrent access.

Example use of the interface:

```ada
{AI95-00433-01} type Fast_Food_Queue is new Queue with record ...;
procedure Append(Q : in out Fast_Food_Queue; Person : in Person_Name);
procedure Remove_First(Q : in out Fast_Food_Queue; Person : outin Person_Name);
function Cur_Count(Q : in Fast_Food_Queue) return Natural;
function Max_Count(Q : in Fast_Food_Queue) return Natural;
...
Cashier, Counter : Fast_Food_Queue;
...
-- Add George (see 3.10.1) to the cashier's queue:
Append (Cashier, George);
-- After payment, move George to the sandwich counter queue:
Transfer (Cashier, Counter);
...
```

An interface such as Queue can be used directly as the parent of a new type (as shown here), or can be used as a progenitor when a type is derived. In either case, the primitive operations of the interface are inherited. For Queue, the implementation of the four inherited routines must be provided. Inside the call of Transfer, calls will dispatch to the implementations of Append and Remove_First for type Fast_Food_Queue.

Example of a task interface:

```ada
type Serial_Device is task interface; -- see 9.1
procedure Read (Dev : in Serial_Device; C : out Character) is abstract;
procedure Write (Dev : in Serial_Device; C : in Character) is abstract;
```

The Serial_Device interface has two dispatching operations which are intended to be implemented by task entries (see 9.1).

Extensions to Ada 95

Interface types are new. They provide multiple inheritance of interfaces, similar to the facility provided in Java and other recent language designs.

Wording Changes from Ada 2005

Correction: Corrected the definition of elaboration for an interface_type_definition to match that of other type definitions.

3.10 Access Types

A value of an access type (an access value) provides indirect access to the object or subprogram it designates. Depending on its type, an access value can designate either subprograms, objects created by allocators (see 4.8), or more generally aliased objects of an appropriate type.
3.10 Access Types

Discussion: A name denotes an entity; an access value designates an entity. The “dereference” of an access value X, written “X.all”, is a name that denotes the entity designated by X.

Language Design Principles

Access values should always be well defined (barring uses of certain unchecked features of Clause Section 13). In particular, uninitialized access variables should be prevented by compile-time rules.

Syntax

access_type_definition ::= [null_exclusion] access_to_object_definition | [null_exclusion] access_to_subprogram_definition

access_to_object_definition ::= access [general_access_modifier] subtype_indication

general_access_modifier ::= all | constant

access_to_subprogram_definition ::= access [protected] procedure parameter_profile | access [protected] function parameter_and_result_profile

Static Semantics

There are two kinds of access types, access-to-object types, whose values designate objects, and access-to-subprogram types, whose values designate subprograms. Associated with an access-to-object type is a storage pool; several access types may share the same storage pool. All descendants of an access type share the same storage pool. A storage pool is an area of storage used to hold dynamically allocated objects (called pool elements) created by allocators; storage pools are described further in 13.11, “Storage Management”.

Access-to-object types are further subdivided into pool-specific access types, whose values can designate only the elements of their associated storage pool, and general access types, whose values can designate the elements of any storage pool, as well as aliased objects created by declarations rather than allocators, and aliased subcomponents of other objects.

Implementation Note: The value of an access type will typically be a machine address. However, a value of a pool-specific access type can be represented as an offset (or index) relative to its storage pool, since it can point only to the elements of that pool.

Access-to-object types are further subdivided into pool-specific access types, whose values can designate only the elements of their associated storage pool, and general access types, whose values can designate the elements of any storage pool, as well as aliased objects created by declarations rather than allocators, and aliased subcomponents of other objects.

Implementation Note: The value of an access type will typically be a machine address. However, a value of a pool-specific access type can be represented as an offset (or index) relative to its storage pool, since it can point only to the elements of that pool.

A view of an object is defined to be aliased if it is defined by an object_declaration, or component_definition, parameter_specification, or extended_return_object_declaration with the reserved word aliased, or by a renaming of an aliased view. In addition, the dereference of an access-to-object value denotes an aliased view, as does a view conversion (see 4.6) of an aliased view. Finally, the current instance of an immutably limited type (see 7.5) isa limited tagged type, a protected type, a task type, or a type that has the reserved word limited in its full definition is also defined to be aliased. Finally, and a formal parameter or generic formal object of a tagged type isare defined to be aliased. [Aliased views are the ones that can be designated by an access value.] If the view defined by an object_declaration is aliased, and the type of the object has discriminants, then the object is constrained; if its nominal subtype is unconstrained, then the object is constrained by its initial value. [Similarly, if the object created by an allocator has discriminants, the object is constrained, either by the designated subtype, or by its initial value.]
Glossary entry: An aliased view of an object is one that can be designated by an access value. Objects allocated by allocators are aliased. Objects can also be explicitly declared as aliased with the reserved word aliased. The Access attribute can be used to create an access value designating an aliased object.

Ramification: The current instance of a nonlimited type is not aliased.

The object created by an allocator is aliased, but not its subcomponents, except of course for those that themselves have aliased in their component_definition.

The renaming of an aliased object is aliased.

Slices are never aliased. See 4.1.2 for more discussion.

Reason: {AI95-00225-01} The current instance of a limited type is defined to be aliased so that an access discriminant of a component can be initialized with T'Access inside the definition of T. Note that we don't want this to apply to a type that could become nonlimited later within its immediate scope, so we require the full definition to be limited.

A formal parameter of a tagged type is defined to be aliased so that a (tagged) parameter X may be passed to an access parameter P by using P => X'Access. Access parameters are most important for tagged types because of dispatching-on-access-parameters (see 3.9.2). By restricting this to formal parameters, we minimize problems associated with allowing components that are not declared aliased to be pointed-to from within the same record.

A view conversion of an aliased view is aliased so that the type of an access parameter can be changed without first converting to a named access type. For example:

```ada
type T1 is tagged ...;  
procedure P(X : access T1);  

type T2 is new T1 with ...;  
procedure P(X : access T2) is 
begin 
  P(T1(X.all)'Access); -- hand off to T1's P 
  ... -- now do extra T2-specific processing 
end P;
```

This paragraph was deleted. {AI95-00363-01} The rule about objects with discriminants is necessary because values of a constrained access subtype can designate an object whose nominal subtype is unconstrained; without this rule, a check on every use of such values would be required to ensure that the discriminants of the object had not changed. With this rule (among others), we ensure that if there might exist aliased views of a discriminated object, then the object is necessarily constrained. Note that this rule is necessary only for untagged types, since a discriminant of a tagged type can't have a default, so all tagged discriminated objects are always constrained anyway.

We considered making more kinds of objects aliased by default. In particular, any object of a by-reference type will pretty much have to be allocated at an addressable location, so it can be passed by reference without using bit-field pointers. Therefore, one might wish to allow the Access and and_Unchecked_Access attributes for such objects. However, private parts are transparent to the definition of “by-reference type”, so if we made all objects of a by-reference type aliased, we would be violating the privacy of private parts. Instead, we would have to define a concept of “visibly by-reference” and base the rule on that. This seemed to complicate the rules more than it was worth, especially since there is no way to declare an untagged limited private type to be by-reference, since the full type might by nonlimited.

Discussion: Note that we do not use the term “aliased” to refer to formal parameters that are referenced through multiple access paths (see 6.2).

An access_to_object_definition defines an access-to-object type and its first subtype; the subtype_indication defines the designated subtype of the access type. If a general_access_modifier appears, then the access type is a general access type. If the modifier is the reserved word constant, then the type is an access-to-constant type; a designated object cannot be updated through a value of such a type. If the modifier is the reserved word all, then the type is an access-to-variable type; a designated object can be both read and updated through a value of such a type. If no general_access_modifier appears in the access_to_object_definition, the access type is a pool-specific access-to-variable type.

To be honest: The type of the designated subtype is called the designated type.

Reason: The modifier all was picked to suggest that values of a general access type could point into “all” storage pools, as well as to objects declared aliased, and that “all” access (both read and update) to the designated object was provided. We couldn't think of any use for pool-specific access-to-constant types, so any access type defined with the modifier constant is considered a general access type, and can point into any storage pool or at other (appropriate) aliased objects.

Implementation Note: The predefined generic Unchecked_Deallocation can be instantiated for any named access-to-variable type. There is no (language-defined) support for deallocating objects designated by a value of an access-to-
An access_to_subprogram_definition defines an access-to-subprogram type and its first subtype; the parameter_profile or parameter_and_result_profile defines the designated profile of the access type. There is a calling convention associated with the designated profile; only subprograms with this calling convention can be designated by values of the access type.}

By default, the calling convention is "protected" if the reserved word protected appears, and "Ada" otherwise. [See Annex B for how to override this default.]

Ramification: The calling convention protected is in italics to emphasize that it cannot be specified explicitly by the user. This is a consequence of it being a reserved word.

Implementation Note: {AI95-00254-01} For a named access-to-subprogram type, the representation of an access value might include implementation-defined information needed to support up-level references — for example, a static link. The accessibility rules (see 3.10.2) ensure that in a "global-display-based" implementation model (as opposed to a static-link-based model), a named access-to-(unprotected)-subprogram value need consist only of the address of the subprogram. The global display is guaranteed to be properly set up any time the designated subprogram is called. Even in a static-link-based model, the only time a static link is definitely required is for an access-to-subprogram type declared in a scope nested at least two levels deep within subprogram or task bodies, since values of such a type might designate subprograms nested a smaller number of levels. For the normal case of a named access-to-subprogram type declared at the outermost (library) level, a code address by itself should be sufficient to represent the access value in many implementations.

For access-to-protected-subprogram, the access values will necessarily include both an address (or other identification) of the code of the subprogram, as well as the address of the associated protected object. This could be thought of as a static link, but it will be needed even for global-display-based implementation models. It corresponds to the value of the "implicit parameter" that is passed into every call of a protected operation, to identify the current instance of the protected type on which they are to operate.

Any Elaboration_Check is performed when a call is made through an access value, rather than when the access value is first "created" via a 'Access. For implementation models that normally put that check at the call-site, an access value will have to point to a separate entry point that does the check. Alternatively, the access value could point to a "subprogram descriptor" that consisted of two words (or perhaps more), the first being the address of the code, the second being the elaboration bit. Or perhaps more efficiently, just the address of the code, but using the trick that the descriptor is initialized to point to a Raise-Program-Error routine initially, and then set to point to the "real" code when the body is elaborated.

For implementations that share code between generic instantiations, the extra level of indirection suggested above to support Elaboration Checks could also be used to provide a pointer to the per-instance data area normally required when calling shared code. The trick would be to put a pointer to the per-instance data area into the subprogram descriptor, and then make sure that the address of the subprogram descriptor is loaded into a "known" register whenever an indirect call is performed. Once inside the shared code, the address of the per-instance data area can be retrieved out of the subprogram descriptor, by indexing off the "known" register.

This paragraph was deleted. {AI95-00344-01} Essentially, the same implementation issues arise for calls on dispatching operations of tagged types, except that the static link is always known "statically.”

Note that access parameters of an anonymous access-to-subprogram type are not permitted. Such if there were such parameters represent, full “downward” closures would be required, meaning that in an implementation that uses a per-task (global) display, the display would have to be passed as a hidden parameter, and reconstructed at the point of call. This was felt to be an undue implementation burden, given that an equivalent (actually, more general) capability is available via formal subprogram parameters to a generic.

An access_definition defines an anonymous general access type or an anonymous access-to-subprogram type. For a general access type access-to-variable type, the subtype_mark denotes its designated subtype; if the general access-modifier constant appears, the type is an access-to-constant type; otherwise, it is an access-to-variable type. For an access-to-subprogram type, the parameter_profile or parameter_and_result_profile denotes
its designated profile. [An access_definition is used in the specification of an access discriminant (see 3.7) or an access parameter (see 6.1).]

{AI95-00230-01} {AI95-00231-01} For each (named) access type, there is a literal null which has a null access value designating no entity at all, which can be obtained by (implicitly) converting the literal null to the access type. [The null value of an anonymous access type is the default initial value of the type.]

NonNull Other values of an access-to-object type are obtained by evaluating an attribute_reference for the Access or Unchecked_Access attribute of an aliased view of an object or nonintrinsic subprogram, or, in the case of a named access-to-object type, an allocator, which returns an access value designating a newly created object (see 3.10.2), or in the case of a general access-to-object type, evaluating an attribute_reference for the Access or Unchecked_Access attribute of an aliased view of an object. Nonnull values of an access-to-subprogram type are obtained by evaluating an attribute_reference for the Access attribute of a nonintrinsic subprogram.

This paragraph was deleted. Ramification. {AI95-00231-01} A value of an anonymous access type (that is, the value of an access parameter or access discriminant) cannot be null.

Reason. {AI95-00231-01} Access parameters allow dispatching on the tag of the object designated by the actual parameter (which gets converted to the anonymous access type as part of the call). In order for dispatching to work properly, there had better be such an object. Hence, the type conversion will raise Constraint_Error if the value of the actual parameter is null.

{AI95-00231-01} A null exclusion in a construct specifies that the null value does not belong to the access subtype defined by the construct, that is, the access subtype excludes null. In addition, the anonymous access subtype defined by the access_definition for a controlling access parameter (see 3.9.2) excludes null. Finally, for a subtype_indication without a null exclusion, the subtype denoted by the subtype_indication excludes null if and only if the subtype denoted by the subtype_mark in the subtype_indication excludes null.

Reason. {AI95-00231-01} An access_definition used in a controlling parameter excludes null because it is necessary to read the tag to dispatch, and null has no tag. We would have preferred to require not_null to be specified for such parameters, but that would have been too incompatible with Ada 95 code to require.

{AI95-00416-01} Note that we considered imposing a similar implicit null exclusion for controlling access results, but chose not to do that, because there is no Ada 95 compatibility issue, and there is no automatic null check inherent in the use of a controlling access result. If a null check is necessary, it is because there is a dereference of the result, or because the value is passed to a parameter whose subtype excludes null. If there is no dereference of the result, a null return value is perfectly acceptable, and can be a useful indication of a particular status of the call.

{8652/0013} {AI95-00012-01} {AI95-00264-1} [All subtypes of an access-to-subprogram type are constrained.] The first subtype of a type defined by an access_definitionaccess_type_definition or an access_to_object_definition is unconstrained if the designated subtype is an unconstrained array or discriminated subtype; otherwise, it is constrained.

Proof: The Legality Rules on range_constraints (see 3.5) do not permit the subtype_mark of the subtype_indication to denote an access-to-scalar type, only a scalar type. The Legality Rules on index_constraints (see 3.6.1) and discriminant_constraints (see 3.7.1) both permit access-to-composite types in a subtype_indication with such constraints. Note that an access-to-access-to-composite is never permitted in a subtype_indication with a constraint.

Reason: {AI95-00363-01} Only composite_constraints are permitted for an access type, and only on access-to-composite types. A constraint on an access-to-scalar or access-to-access type might be violated due to assignments via other access paths that were not so constrained. By contrast, if the designated subtype is an array or discriminated type without defaults, the constraint could not be violated by unconstrained assignments, since array objects are always constrained, and aliased discriminated objects are also constrained when the type does not have defaults for its discriminants. Constraints are not allowed on general access-to-unconstrained discriminated types if the type has defaults for its discriminants; constraints on pool-specific access types are usually allowed because allocated objects are usually constrained by their initial value (by fiat, see Static Semantics).
Legality Rules

If a subtype_indication, discriminant_specification, parameter_specification, parameter_and_result_profile, object_renaming_declaration, or formal_object_declaration has a null-exclusion, the subtype_mark in that construct shall denote an access subtype that does not exclude null.

To be honest: This means “directly allowed in”; we are not talking about a null_exclusion that occurs in an access_definition in one of these constructs (for an access_definition, the subtype_mark in such an access_definition is not restricted).

Reason: This is similar to doubly constraining a composite subtype, which we also don't allow.

Dynamic Semantics

A composite_constraint is compatible with an unconstrained access subtype if it is compatible with the designated subtype. A null_exclusion is compatible with any access subtype that does not exclude null. An access value satisfies a composite_constraint of an access subtype if it equals the null value of its type or if it designates an object whose value satisfies the constraint. An access value satisfies an exclusion of the null value if it does not equal the null value of its type.

The elaboration of an access_type_definition creates the access type and its first subtype. For an access-to-object type, this elaboration includes the elaboration of the subtype_indication, which creates the designated subtype.

The elaboration of an access_definition creates an anonymous general_access-to-variable type {{this happens as part of the initialization of an access parameter or access_discriminant}}.

NOTES

83 Access values are called “pointers” or “references” in some other languages.
84 Each access-to-object type has an associated storage pool; several access types can share the same pool. An object can be created in the storage pool of an access type by an allocator (see 4.8) for the access type. A storage pool (roughly) corresponds to what some other languages call a “heap.” See 13.11 for a discussion of pools.
85 Only index_constraints and discriminant_constraints can be applied to access types (see 3.6.1 and 3.7.1).

Examples

Examples of access-to-object types:

- type Peripheral_Ref is not null access Peripheral; -- see 3.8.1
- type Binop_Ptr is access all Binary_Operation'Class; -- general access-to-class-wide, see 3.9.1

Example of an access subtype:

- subtype Drum_Ref is Peripheral_Ref(Drum); -- see 3.8.1

Example of an access-to-subprogram type:

- type Message_Procedure is access procedure (M : in String := "Error!");
- procedure Default_Message_Procedure(M : in String);
- ...
- procedure Other_Procedure(M : in String);
- ...
- Give_Message("File not found."); -- call with parameter (all is optional)
- Give_Message.all; -- call with no parameters

Extensions to Ada 83

The syntax for access_type_definition is changed to support general access types (including access-to-constants) and access-to-subprograms. The syntax rules for general_access_modifier and access_definition are new.
3.10 Wording Changes from Ada 83

We use the term "storage pool" to talk about the data area from which allocation takes place. The term "collection" is only used for finalization no longer used. ("Collection" and "storage pool" are not the same thing because multiple unrelated access types can share the same storage pool; see 13.11 for more discussion.)

Inconsistencies With Ada 95

Access discriminants and noncontrolling access parameters no longer exclude null. A program which passed null to such an access discriminant or access parameter and expected it to raise Constraint_Error may fail when compiled with Ada 2005. One hopes that there no such programs outside of the ACATS. (Of course, a program which actually wants to pass null will work, which is far more likely.)

Most unconstrained aliased objects with defaulted discriminants are no longer constrained by their initial values. This means that a program that raised Constraint_Error from an attempt to change the discriminants will no longer do so. The change only affects programs that depended on the raising of Constraint_Error in this case, so the inconsistency is unlikely to occur outside of the ACATS. This change may however cause compilers to implement these objects differently, possibly taking additional memory or time. This is unlikely to be worse than the differences caused by any major compiler upgrade.

Incompatibilities With Ada 95

Amendment Correction: The rule defining when a current instance of a limited type is considered to be aliased has been tightened to apply only to types that cannot become nonlimited. A program that attempts to take 'Access of the current instance of a limited type that can become nonlimited will be illegal in Ada 2005. While original Ada 95 allowed the current instance of any limited type to be treated as aliased, this was inconsistently implemented in compilers, and was likely to not work as expected for types that are ultimately nonlimited.

Extensions to Ada 95

The null exclusion is new. It can be used in both anonymous and named access type definitions. It is most useful to declare that parameters cannot be null, thus eliminating the need for checks on use.

The kinds of anonymous access types allowed were increased by adding anonymous access-to-constant and anonymous access-to-subprogram types. Anonymous access-to-subprogram types used as parameters allow passing of subprograms at any level.

Wording Changes from Ada 95

Corrigendum: Added accidentally-omitted wording that says that a derived access type shares its storage pool with its parent type. This was clearly intended, both because of a note in 3.4, and because anything else would have been incompatible with Ada 83.

Corrigendum: Fixed typographical errors in the description of when access types are constrained.

The wording was fixed to allow allocators and the literal null for anonymous access types. The former was clearly intended by Ada 95; see the Implementation Advice in 13.11.

The rules about aliased objects being constrained by their initial values now apply only to allocated objects, and thus have been moved to 4.8, "Allocators".

Wording Changes from Ada 2005

Correction: The rule about a current instance being aliased now is worded in terms of immutably limited types. Wording was also added to make extended return object declarations that have the keyword aliased be considered aliased. This latter was a significant oversight in Ada 2005 — technically, the keyword aliased had no effect. But of course implementations followed the intent, not the letter of the Standard.

Explicitly aliased parameters (see 6.1) are defined to be aliased.

3.10.1 Incomplete Type Declarations

There are no particular limitations on the designated type of an access type. In particular, the type of a component of the designated type can be another access type, or even the same access type. This permits mutually dependent and recursive access types. An incomplete_type_declaration can be used to introduce a type to be used as a designated type, while deferring its full definition to a subsequent full_type_declaration.
3.10.1 Incomplete Type Declarations

Syntax

\{AI95-00326-01\} incomplete_type_declaration ::= type defining_identifier [discriminant_part] \{is tagged\};

Static Semantics

\{AI95-00326-01\} An incomplete_type_declaration declares an incomplete view of a type and its first subtype; the first subtype is unconstrained if a discriminant_part appears. If the incomplete_type_declaration includes the reserved word tagged, it declares a tagged incomplete view. [An incomplete view of a type is a limited view of the type (see 7.5).]

\{AI95-00326-01\} Given an access type A whose designated type T is an incomplete view, a dereference of a value of type A also has this incomplete view except when:

Discussion: \{AI05-0208-1\} Whether the designated type is an incomplete view (and thus whether this set of rules applies) is determined by the view of the type at the declaration of the access type; it does not change during the life of the type.

- it occurs within the immediate scope of the completion of T, or
- \{AI05-0208-1\} it occurs within the scope of a nonlimited with_clause that mentions a library package in whose visible part the completion of T is declared, or.
- \{AI05-0208-1\} it occurs within the scope of the completion of T and T is an incomplete view declared by an incomplete_type_declaration.

\{AI05-0162-1\} In these cases, the dereference has the full view of T visible at the point of the dereference.

Discussion: We need the “in whose visible part” rule so that the second rule doesn't trigger in the body of a package with a with of a child unit:

package P is
  private
  type T;  -- type PtrT is access T;
  end P;

private package P.C is
  P : PtrT;
  end P.C;

\{AI05-0005-1\} with P.C;
package body P is
  -- Ptr.all'Size is not legal here, but we are within it in the scope of a nonlimited with_clause for P.
  -- of a nonlimited with_clause for P.
  type T is . . . ;
  -- Ptr.all'Size is legal here.
  end P;

\{AI95-00412-01\} \{AI05-0162-1\} \{AI05-0208-1\} Similarly, if a subtype_mark denotes a subtype_declaration defining a subtype of an incomplete view T, the subtype_mark denotes an incomplete view except under the same three circumstances given above, in which case it denotes the full view of T visible at the point of the subtype_mark.

Legality Rules

\{AI05-0162-1\} An incomplete_type_declaration requires a completion, which shall be a type_declaration other than an incomplete_type_declaration full_type_declaration. [If the incomplete_type_declaration occurs immediately within either the visible part of a package_specification or a declarative_part, then the type_declaration full_type_declaration shall occur later and immediately within this visible part or declarative_part. If the incomplete_type_declaration occurs immediately within the private part of a given package_specification, then the type_declaration full_type_declaration shall occur later and immediately within either the private part itself, or the declarative_part of the corresponding package_body.]
{AI95-00326-01} {AI05-0162-1} If an incomplete_type_declaration includes the reserved word tagged, then a type_declaration full_type_declaration that completes it shall declare a tagged_type. If an incomplete_type_declaration has a known_discriminant_part, then a type_declaration full_type_declaration that completes it shall have a fully conforming (explicit) known_discriminant_part (see 6.3.1). [If an incomplete_type_declaration has no discriminant_part (or an unknown_discriminant_part), then a corresponding type_declaration full_type_declaration is nevertheless allowed to have discriminants, either explicitly, or inherited via derivation.]

{AI95-00326-01} The only allowed uses of a name that denotes an incomplete_view of a type may be used incomplete_type_declaration are as follows:

- {AI95-00326-01} as the subtype_mark in the subtype_indication of an access_to_object_definition; [the only form of constraint allowed in this subtype_indication is a discriminant_constraint ([a null_exclusion is not allowed]);]

  Implementation Note: We now allow discriminant_constraints even if the full type is deferred to the package body. However, there is no particular implementation burden because we have dropped the concept of the dependent compatibility check. In other words, we have effectively repealed AI83-00007.

- {AI95-00326-01} {AI95-00412-01} as the subtype_mark in the subtype_indication of a subtype_declaration; the subtype_indication shall not have a null_exclusion or a constraint defining the subtype of a parameter or result of an access_to_subprogram_definition;

  Reason: {AI95-00326-01} This allows, for example, a record to have a component designating a subprogram that takes that same record type as a parameter.

- {AI95-00326-01} {AI95-05151-1} as the subtype_mark in an access_definition for an access-to-object_type;

  To be honest: This does not mean any random subtype_mark in a construct that makes up an access_definition, such as a formal_part, just the one given directly in the syntax of access_definition.

- {AI95-05151-1} as the subtype_mark defining the subtype of a parameter or result in a profile occurring within a basic_declaration;

  Ramification: But not in the profile for a body or entry.

- {AI95-00326-01} as a generic actual parameter whose corresponding generic formal parameter is a formal incomplete_type (see 12.5.1).

{AI95-00326-01} If such a name denotes a tagged incomplete view, it may also be used:

- {AI95-00326-01} {AI95-0151-1} as the subtype_mark defining the subtype of a parameter in the profile for a subprogram_body, entry_body, or accept_statement_formal_part;

- {AI95-00326-01} as the prefix of an attribute_reference whose attribute_designator is Class; such an attribute_reference is similarly restricted to the uses allowed here; it denotes a tagged incomplete_view when used in this way, the corresponding full_type_declaration shall declare a tagged_type, and the attribute_reference shall occur in the same library unit as the incomplete_type_declaration.

This paragraph was deleted. Reason: {AI95-00326-01} This is to prevent children from imposing requirements on their ancestor library units for deferred incomplete types.
If such a name occurs within the declaration list containing the completion of the incomplete view, it may also be used:

• This paragraph was deleted.

This paragraph was deleted.

Reason: This allows, for example, a record to have a component designating a subprogram that takes that same record type as a parameter.

If any of the above uses occurs as part of the declaration of a primitive subprogram of the incomplete view, and the declaration occurs immediately within the private part of a package, then the completion of the incomplete view shall also occur immediately within the private part; it shall not be deferred to the package body.

Reason: This fixes a hole in Ada 95 where a dispatching operation with an access parameter could be declared in a private part and a dispatching call on it could occur in a child even though there is no visibility on the full type, requiring access to the controlling tag without access to the representation of the type.

No other uses of a name that denotes an incomplete view of a type are allowed.

A prefix that denotes an objectA dereference (whether implicit or explicit—see 4.1) shall not be of an incomplete view type. An actual parameter in a call shall not be of an untagged incomplete view. The result object of a function call shall not be of an incomplete view. A prefix shall not denote a subprogram having a formal parameter of an untagged incomplete view, nor a return type that is an incomplete view.

Reason: We used to disallow all dereferences of an incomplete type. Now we only disallow such dereferences when used as a prefix. Dereferences used in other contexts do not pose a problem since normal type matching will preclude their use except when the full type is “nearby” as context (for example, as the expected type).

This also disallows prefixes that are directly of an incomplete view. For instance, a parameter \( P \) can be declared of a tagged incomplete type, but we don’t want to allow \( P\text{'Size}, P\text{'Alignment} \), or the like, as representation values aren’t known for an incomplete view.

We say “denotes an object” so that prefixes that directly name an incomplete view are not covered; the previous rules cover such cases, and we certainly don’t want to ban Incomp‘Class.

As subprogram profiles now may include any kind of incomplete type, we also disallow passing objects of untagged incomplete types in subprogram calls (as the parameter passing method is not known as it is for tagged types) and disallow returning any sort of incomplete objects (since we don’t know how big they are).

Static Semantics

An incomplete_type_declaration declares an incomplete type and its first subtype; the first subtype is unconstrained if a known_discriminant_part appears.

Reason: If an unknown_discriminant_part or no discriminant_part appears, then the constrainedness of the first subtype doesn’t matter for any other rules or semantics, so we don’t bother defining it. The case with a known_discriminant_part is the only case in which a constraint could later be given in a subtype_indication naming the incomplete type.

Paragraph 11 was deleted.

Dynamic Semantics

The elaboration of an incomplete_type_declaration has no effect.

Reason: An incomplete type has no real existence, so it doesn't need to be "created" in the usual sense we do for other types. It is roughly equivalent to a "forward;" declaration in Pascal. Private types are different, because they have a different set of characteristics from their full type.

NOTES

86 Within a declarative_part, an incomplete_type_declaration and a corresponding full_type_declaration cannot be separated by an intervening body. This is because a type has to be completely defined before it is frozen, and a body freezes all types declared prior to it in the same declarative_part (see 13.14).
A name that denotes an object of an incomplete view is defined to be of a limited type. Hence, the target of an assignment statement cannot be of an incomplete view.

**Examples**

**Example of a recursive type:**

```ada
type Cell; -- incomplete type declaration
type Link is access Cell;
type Cell is record
  Value  : Integer;
  Succ   : Link;
  Pred   : Link;
end record;
Head : Link := new Cell'(0, null, null);
Next  : Link := Head.Succ;
```

**Examples of mutually dependent access types:**

```ada
{AI95-00433-01} type Person<>; -- incomplete type declaration
type Car is tagged; -- incomplete type declaration
{AI95-00433-01} type Person_Name is access Person;
type Car_Name is access all Car'Class;
{AI95-00433-01} type Car is tagged record
  Number  : Integer;
  Owner   : Person_Name;
end record;
type Person(Sex : Gender) is record
  Name     : String(1 .. 20);
  Birth    : Date;
  Age      : Integer range 0 .. 130;
  Vehicle  : Car_Name;
  case Sex is
    when M => Wife           : Person_Name(Sex => F);
    when F => Husband        : Person_Name(Sex => M);
  end case;
end record;
My_Car, Your_Car, Next_Car : Car_Name := new Car; -- see 4.8
George : Person_Name := new Person(M);
...
George.Vehicle := Your_Car;
```

**Extensions to Ada 83**

The full_type_declaraiton that completes an incomplete_type_declaraiton may have a known_discriminant_part even if the incomplete_type_declaraiton does not.

A discriminant_constraint may be applied to an incomplete type, even if its completion is deferred to the package body, because there is no “dependent compatibility check” required any more. Of course, the constraint can be specified only if a known_discriminant_part was given in the incomplete_type_declaraiton. As mentioned in the previous paragraph, that is no longer required even when the full type has discriminants.

**Wording Changes from Ada 83**

Dereferences producing incomplete types were not explicitly disallowed in RM83, though AI83-00039 indicated that it was not strictly necessary since troublesome cases would result in Constraint_Error at run time, since the access value would necessarily be null. However, this introduces an undesirable implementation burden, as illustrated by Example 4 of AI83-00039:
package Pack is
  type Pri is private;
private
  type Sep;
  type Pri is access Sep;
  X : Pri;
end Pack;

package body Pack is
  -- Could be separately compiled!
  type Sep is ...;
  X := new Sep;
end Pack;

pragma Elaborate(Pack);
private package Pack.Child is
  I : Integer := X.all'Size; -- Legal, by AI-00039.
end Pack.Child;

Generating code for the above example could be a serious implementation burden, since it would require all aliased objects to store size dope, and for that dope to be in the same format for all kinds of types (or some other equivalently inefficient implementation). On the contrary, most implementations allocate dope differently (or not at all) for different designated subtypes.

Incompatibilities With Ada 95

{AI95-00326-01} It is now illegal to use an incomplete view (type) as the parameter or result of an access-to-subprogram type unless the incomplete view is completed in the same declaration list as the use. This was allowed in Ada 95 for incomplete types where the completion was deferred to the body. By disallowing this rare use of incomplete views, we can allow the use of incomplete views in many more places, which is especially valuable for limited views.

{AI95-00326-01} It is now illegal to use an incomplete view (type) in a primitive subprogram of the type unless the incomplete view is completed in the package specification. This was allowed in Ada 95 for incomplete types where the completion was deferred to the body (the use would have to be in an access parameter). This incompatibility was caused by the fix for the hole noted in Legality Rules above.

Extensions to Ada 95

{AI95-00326-01} Tagged incomplete types are new. They are allowed in parameter declarations as well as the usual places, as tagged types are always by-reference types (and thus there can be no code generation issue).

{AI95-00412-01} A subtype declaration can be used to give a new name to an incomplete view of a type. This is valuable to give shorter names to entities imported with a limited with_clause.

Wording Changes from Ada 95

{AI95-00326-01} The description of incomplete types as incomplete views is new. Ada 95 defined these as separate types, but neglected to give any rules for matching them with other types. Luckily, implementers did the right thing anyway. This change also makes it easier to describe the meaning of a limited view.

Extensions to Ada 2005

{AI05-00098-1} Correction: Fixed the definition so that an anonymous access-to-subprogram type can use an incomplete view in the same way that a named access-to-subprogram type can.

{AI05-0151-1} Incomplete types now can be used in subprogram declarations. The type has to be complete before any calls or the body is declared. This reduces the places where access types are required for types imported from limited views of packages.

{AI05-0162-1} Incomplete types now can be completed by private types and private extensions. Since this can already happen for limited views, there is no remaining reason to disallow it for explicitly declared incomplete types.

Wording Changes from Ada 2005

{AI05-0208-1} Correction: Changed the rules of uses of dereferences of incomplete views such that it does not introduce an unintentional incompatibility with Ada 83 and Ada 95.

{AI05-0213-1} Incomplete types now can be used as actuals to formal incomplete types (see 12.5.1).
3.10.2 Operations of Access Types

{AI05-0299-1} [The attribute Access is used to create access values designating aliased objects and nonintrinsic subprograms. The “accessibility” rules prevent dangling references (in the absence of uses of certain unchecked features — see Clause Section 13).]

Language Design Principles

It should be possible for an access value to designate an object declared by an object declaration, or a subcomponent thereof. In implementation terms, this means pointing at stack-allocated and statically allocated data structures. However, dangling references should be prevented, primarily via compile-time rules, so long as features like Unchecked_Access and Unchecked_Deallocation are not used.

In order to create such access values, we require that the access type be a general access type, that the designated object be aliased, and that the accessibility rules be obeyed.

Name Resolution Rules

{AI95-00235-01} For an attribute_reference with attribute_designator Access (or Unchecked_Access — see 13.10), the expected type shall be a single access type A such that: {the prefix of such an attribute_reference is never interpreted as an implicit_dereference}. If the expected type is an access-to-subprogram type, then the expected profile of the prefix is the designated profile of the access type.

- {AI95-00235-01} A is an access-to-object type with designated type D and the type of the prefix is D'Class or is covered by D, or
- {AI95-00235-01} A is an access-to-subprogram type whose designated profile is type conformant with that of the prefix.

{AI95-00235-01} [The prefix of such an attribute_reference is never interpreted as an implicit dereference or a parameterless function_call (see 4.1.4).] The designated type or profile of the expected type of the attribute_reference is the expected type or profile for the prefix.

Discussion: Saying that the expected type shall be a "single access type" is our "new" way of saying that the type has to be determinable from context using only the fact that it is an access type. See 4.2 and 8.6. Specifying the expected profile only implies type conformance. The more stringent subtype conformance is required by a Legality Rule. This is the only Resolution Rule that applies to the name in a prefix of an attribute_reference. In all other cases, the name has to be resolved without using context. See 4.1.4.

{AI95-00235-01} Saying “single access type” is a bit of a fudge. Both the context and the prefix may provide both multiple types; “single” only means that a single, specific interpretation must remain after resolution. We say “single” here to trigger the Legality Rules of 8.6. The resolution of an access attribute is similar to that of an assignment_statement. For example:

```ada
type Int_Ptr is access all Integer;
type Char_Ptr is access all Character;
type Float_Ptr is access all Float;
function Zap (Val : Int_Ptr) return Float; -- (1)
function Zap (Val : Float_Ptr) return Float; -- (2)
function Zop return Int_Ptr; -- (3)
function Zop return Char_Ptr; -- (4)
Result : Float := Zap (Zop.all'Access); -- Resolves to Zap (1) and Zop (3).
```

Static Semantics

{AI95-00162-01} [The accessibility rules, which prevent dangling references, are written in terms of accessibility levels, which reflect the run-time nesting of masters. As explained in 7.6.1, a master is the execution of a certain construct, such as task_body, a block_statement, a subprogram_body, an entry_body, or an accept_statement. An accessibility level is deeper than another if it is more deeply nested at run time. For example, an object declared local to a called subprogram has a deeper accessibility level than an object declared local to the calling subprogram. The accessibility rules for access types require that the accessibility level of an object designated by an access value be no deeper than that of the...]

161 13 December 2012 Operations of Access Types 3.10.2
access type. This ensures that the object will live at least as long as the access type, which in turn ensures that the access value cannot later designate an object that no longer exists. The Unchecked_Access attribute may be used to circumvent the accessibility rules.

Discussion: The Unchecked_Access attribute acts as if the object was declared at library-level; this applies even when it is used as the value of anonymous access type. See 13.10.

Subclause 3.10.2, home of the accessibility rules, is informally known as the “Heart of Darkness” amongst the maintainers of Ada. Woe unto all who enter here (well, at least unto anyone that needs to understand any of these rules).

A given accessibility level is said to be statically deeper than another if the given level is known at compile time (as defined below) to be deeper than the other for all possible executions. In most cases, accessibility is enforced at compile time by Legality Rules. Run-time accessibility checks are also used, since the Legality Rules do not cover certain cases involving access parameters and generic packages.

Each master, and each entity and view created by it, has an accessibility level:

- The accessibility level of a given master is deeper than that of each dynamically enclosing master, and deeper than that of each master upon which the task executing the given master directly depends (see 9.3).

- An entity or view defined and created as part of its elaboration has the same accessibility level as the innermost enclosing master of the declaration except in the cases of renaming and derived access types described below. Other than for an explicitly aliased parameter, a formal parameter of a callable entity master has the same accessibility level as the master representing the invocation of the entity.

- The accessibility level of a view of an object or subprogram defined by a renaming declaration is the same as that of the renamed view.

- The accessibility level of a view conversion, qualified expression, or parenthesized expression, is the same as that of the operand.

- The accessibility level of a conditional expression is the accessibility level of the evaluated dependent expression.
• \{AI95-00318-02\} \{AI95-00416-01\} \{AI05-0234-1\} The accessibility level of the result object is the same as that of the master that elaborated the function body. For any other function, the accessibility level of an aggregate or the result of a function call (or equivalent use of an operator) that is used (in its entirety) to directly initialize part of another object is that of the object being initialized. In other contexts, the accessibility level of an aggregate or the result of a function call is that of the innermost master that evaluates the aggregate or function call execution of the called function.

• \{AI05-0234-1\} The accessibility level of the result of a function call is that of the master of the function call, which is determined by the point of call as follows:
  
  • If the result is used (in its entirety) to directly initialize part of an object, the master is that of the object being initialized. In the case where the initialized object is a coextension (see below) that becomes a coextension of another object, the master is that of the eventual object to which the coextension will be transferred.

  **To be honest:** \{AI95-00416-01\} The first sentence is talking about a static use of the entire return object — a slice that happens to be the entire return object doesn’t count. On the other hand, this is intended to allow parentheses and qualified expressions.

  **Ramification:** \{AI95-00416-01\} \{AI05-0234-1\} If the function is used as a prefix, this bullet does not apply. Similarly, an assignment statement is not an initialization of an object, so this bullet does not apply.

  • If the result is of an anonymous access type and is the operand of an explicit conversion, the master is that of the target type of the conversion;

  • If the result is of an anonymous access type and defines an access discriminant, the master is the same as that for an object created by an anonymous allocator that defines an access discriminant (even if the access result is of an access-to-subprogram type).

  • If the call itself defines the result of a function to which one of the above rules applies, these rules are applied recursively;

  • In other cases, the master of the call is that of the innermost master that evaluates the function call.

  **Ramification:** \{AI95-00318-02\} \{AI95-00416-01\} The “innermost master which evaluated the function call” does not include the function call itself (which might be a master).

\{AI95-00318-02\} \{AI95-00416-01\} We really mean the innermost master here, which could be a very short lifetime. Consider a function call used as a parameter of a procedure call. In this case the innermost master which evaluated the function call is the procedure call.

  **Ramification:** \{AI05-0234-1\} These rules do not mention whether the result object is built-in-place (see 7.6). In particular, in the case where building in place is optional, the choice whether or not to build-in-place has no effect on masters, lifetimes, or accessibility.

  **Implementation Note:** \{AI05-0234-1\} There are several cases where the implementation may have to pass in the accessibility level of the result object on a call, to support later rules where the accessibility level comes from the master of the call:

  • when the function result may have a part with access discriminants;

  • when the function result type is an anonymous access type;

  • when the function result is built-in-place;

  • when the function has an explicitly aliased parameter.

  In particular, this implies passing a level parameter when the result type is class-wide, since descendants may add access discriminants. For most implementations this will mean that functions with controlling results will also need a level parameter.

\{AI05-0284-1\} In the case of a call to a function whose result type is an anonymous access type, the accessibility level of the type of the result of the function call is also determined by the point of call as described above.
3.10.2 Operations of Access Types

• `{AI95-00416-01}` Within a return statement, the accessibility level of the return object is that of the execution of the return statement. If the return statement completes normally by returning from the function, then prior to leaving the function, the accessibility level of the return object changes to be a level determined by the point of call, as does the level of any coextensions (see below) of the return object.

**Reason:** We define the accessibility level of the return object during the return statement to be that of the return statement itself so that the object may be designated by objects local to the return statement, but not by objects outside the return statement. In addition, the intent is that the return object gets finalized if the return statement ends without actually returning (for example, due to propagating an exception, or a goto). For a normal return, of course, no finalization is done before returning.

• The accessibility level of a derived access type is the same as that of its ultimate ancestor.

• `{AI95-00230-01}` The accessibility level of the anonymous access type defined by an access_definition of an object_renaming_declaration is the same as that of the renamed view.

• `{AI95-00230-01}` `{AI95-00416-01}` The accessibility level of the anonymous access type of an access discriminant in the subtype_indication or qualified_expression of an allocator, or in the expression or return_subtype_indication of a return statement is determined as follows:

  - If the value of the access discriminant is determined by a discriminant_association in a subtype_indication, the accessibility level of the object or subprogram designated by the associated value (or library level if the value is null);

**Discussion:** This deals with the following cases, when they occur in the context of an allocator or return statement:

  • An extension_aggregate where the ancestor_part is a subtype_mark denoting a constrained subtype;

  • An uninitialized allocator where the subtype_indication defines a constrained subtype;

  • A discriminant of an object with a constrained nominal subtype, including constrained components, the result of calling a function with a constrained result subtype, the dereference of an access-to-constrained subtype, etc.

**Ramification:** `{AI05-0281-1}` The subtype_indication mentioned in this bullet is not necessarily the one given in the allocator or return statement that is determining the accessibility level; the constrained subtype might have been defined in an earlier declaration (as a named subtype).

• `{AI05-0005-1}` If the value for this rule and the next one is derived from an Unchecked Access attribute, the accessibility is library-level no matter what the accessibility level of the object is (see 13.10).

• `{AI05-0234-1}` If the value of the access discriminant is determined by a default_expression in the declaration of the discriminant, the level of the object or subprogram designated by the associated value (or library level if null);

**Discussion:** This covers the case of an unconstrained subcomponent of a limited type with defaulted access discriminants.

• `{AI05-0004-1}` If the value of the access discriminant is determined by a record_component_association in an aggregate, the accessibility level of the object or subprogram designated by the associated value (or library level if the value is null);

**Discussion:** In this bullet, the aggregate has to occur in the context of an allocator or return statement, while the subtype_indication of the previous bullet can occur anywhere (it doesn't have to be directly given in the allocator or return statement).

• In other cases, where the value of the access discriminant is determined by an object with an unconstrained nominal subtype, the accessibility level of the object.

**Discussion:** `{AI95-00416-01}` In other words, if you know the value of the discriminant for an allocator or return statement from a discriminant constraint or an aggregate component association, then that determines the accessibility level; if you don't know it, then it is based on the object itself.

• `{AI95-00416-01}` The accessibility level of the anonymous access type of an access discriminant in any other context is that of the enclosing object.
The accessibility level of the anonymous access type of an access parameter specifying an access-to-object type is the same as that of the view designated by the actual (or library-level if the actual is null). If the actual is an allocator, this is the accessibility level of the execution of the called subprogram.

Reason: These represent “downward closures” and thus require passing of static links or global display information (along with generic sharing information if the implementation does sharing) along with the address of the subprogram. We must prevent conversions of these to types with “normal” accessibility, as those typically don’t include the extra information needed to make a call.

The accessibility level of the anonymous access type of an access parameter specifying an access-to-subprogram type is deeper than that of any master; all such anonymous access types have this same level.

Reason: These represent “downward closures” and thus require passing of static links or global display information (along with generic sharing information if the implementation does sharing) along with the address of the subprogram. We must prevent conversions of these to types with “normal” accessibility, as those typically don’t include the extra information needed to make a call.

The accessibility level of the type of a stand-alone object of an anonymous access-to-object type is the same as the accessibility level of the type of the access value most recently assigned to the object; accessibility checks ensure that this is never deeper than that of the declaration of the stand-alone object.

The accessibility level of an explicitly aliased (see 6.1) formal parameter in a function body is determined by the point of call; it is the same level that the return object ultimately will have.

The accessibility level of an object created by an allocator is the same as that of the access type, except for an allocator of an anonymous access type (an anonymous allocator) in certain contexts, as follows: For an anonymous allocator that defines the result of a function with an access result, the accessibility level is determined as though the allocator were in place of the call of the function; in the special case of a call that is the operand of a type conversion, the level is that of the target access type of the conversion that defines the value of an access parameter or an access discriminant. For an anonymous allocator defining the value of an access parameter, the accessibility level is that of the innermost master of the call. For an anonymous allocator whose type is that of a stand-alone object of an anonymous access-to-object type, the accessibility level is that of the declaration of the stand-alone object. For one defining an access discriminant, the accessibility level is determined as follows:

- For an allocator used to define the discriminant of an object, the level of the object constraint in a subtype declaration, the level of the subtype declaration:

- For an allocator used to define the constraint in a subtype indication component definition, the level of the enclosing type:

This paragraph was deleted.

In the first this last case, the allocated object is said to be a coextension of the object whose discriminant designates it, as well as of any object of which the discriminated object is itself a coextension or subcomponent. If the allocated object is a coextension of an anonymous object representing the result of an aggregate or function call that is used (in its entirety) to directly initialize a part of an object, after the result is assigned, the coextension becomes a coextension of the object being initialized and is no longer considered a coextension of the anonymous object. All coextensions of an object [(which have not thus been transferred by such an initialization)] are finalized when the object is finalized (see 7.6.1).

Ramification: The rules of access discriminants are such that when the space for an object with a coextension is reclaimed, the space for the coextensions can be reclaimed. Hence, there is implementation advice (see 13.11) that an
object and its coextensions all be allocated from the same storage pool (or stack frame, in the case of a declared object).

- **AI05-0051-1** Within a return statement, the accessibility level of the anonymous access type of an access result is that of the master of the call.

- **AI05-0014-1** The accessibility level of a view of an object or subprogram denoted by a dereference of an access value is the same as that of the access type.

**Discussion:** **AI05-0005-1** **AI05-0014-1** This rule applies even when no dereference exists, for example when an access value is passed as an access parameter. This rule ensures that implementations are not required to include dynamic accessibility values with all access values.

- The accessibility level of a component, protected subprogram, or entry of (a view of) a composite object is the same as that of (the view of) the composite object.

- **AI95-00416-01** **AI05-0262-1** In the above rules, the operand of a view conversion, parenthesized expression or qualified expression is considered to be used in a context if the view conversion, parenthesized expression or qualified expression itself is used in that context. Similarly, a dependent expression of a conditional expression is considered to be used in a context if the conditional expression itself is used in that context.

One accessibility level is defined to be **statically deeper** than another in the following cases:

- For a master that is statically nested within another master, the accessibility level of the inner master is statically deeper than that of the outer master.

  **To be honest:** Strictly speaking, this should talk about the constructs (such as subprogram_bodies) being statically nested within one another; the masters are really the executions of those constructs.

  **To be honest:** If a given accessibility level is statically deeper than another, then each level defined to be the same as the given level is statically deeper than each level defined to be the same as the other level.

- **AI95-00254-01** The accessibility level of the anonymous access type of an access parameter specifying an access-to-subprogram type is statically deeper than that of any master; all such anonymous access types have this same level.

  **Ramification:** This rule means that it is illegal to convert an access parameter specifying an access to subprogram to a named access to subprogram type, but it is allowed to pass such an access parameter to another access parameter (the implicit conversion’s accessibility will succeed).

- **AI95-00254-01** **AI05-0082-1** The statically deeper relationship does not apply to the accessibility level of the anonymous type of an access parameter specifying an access-to-object type nor does it apply to a descendant of a generic formal type; that is, such an accessibility level is not considered to be statically deeper, nor statically shallower, than any other.

  **Ramification:** In these cases, we use dynamic accessibility checks.

- **AI05-0148-1** The statically deeper relationship does not apply to the accessibility level of the type of a stand-alone object of an anonymous access-to-object type; that is, such an accessibility level is not considered to be statically deeper, nor statically shallower, than any other.

- **AI05-0142-4** **AI05-0235-1** Inside a return statement that applies to a function \( F \), when determining whether the accessibility level of an explicitly aliased parameter of \( F \) is statically deeper than the level of the return object of \( F \), the level of the return object is considered to be the same as that of the level of the explicitly aliased parameter; for statically comparing with the level of other entities, an explicitly aliased parameter of \( F \) is considered to have the accessibility level of the body of \( F \).

- **AI05-0051-1** **AI05-0234-1** **AI05-0235-1** For determining whether a level is statically deeper than the level of the anonymous access type of an access result of a function, when within a return statement that applies to the function, the level of the master of the call is presumed to be the same as that of the level of the master that elaborated the function body.
To be honest: This rule has no effect if the previous bullet also applies (that is, the “a level” is of an explicitly aliased parameter).

- [For determining whether one level is statically deeper than another when within a generic package body, the generic package is presumed to be instantiated at the same level as where it was declared; run-time checks are needed in the case of more deeply nested instantiations.]

Proof: A generic package does not introduce a new master, so it has the static level of its declaration; the rest follows from the other "statically deeper" rules.

- For determining whether one level is statically deeper than another when within the declarative region of a type_declaration, the current instance of the type is presumed to be an object created at a deeper level than that of the type.

Ramification: In other words, the rules are checked at compile time of the type_declaration, in an assume-the-worst manner.

The accessibility level of all library units is called the library level; a library-level declaration or entity is one whose accessibility level is the library level.

Ramification: Library_unit_declarations are library level.Nested declarations are library level if they are nested only within packages (possibly more than one), and not within subprograms, tasks, etc.

To be honest: The definition of the accessibility level of the anonymous type of an access parameter specifying an access-to-object type cheats a bit, since it refers to the view designated by the actual, but access values designate objects, not views of objects. What we really mean is the view that “would be” denoted by an expression “X.all”, where X is the actual, even though such an expression is a figment of our imagination. The definition is intended to be equivalent to the following more verbose version: The accessibility level of the anonymous type of an access parameter is as follows:

- if the actual is an expression of a named access type — the accessibility level of that type;
- if the actual is an allocator — the accessibility level of the execution of the called subprogram;
- if the actual is a reference to the Access attribute — the accessibility level of the view denoted by the prefix.
- if the actual is a reference to the Unchecked_Access attribute — library accessibility level;
- if the actual is an access parameter — the accessibility level of its type.

Note that the allocator case is explicitly mentioned in the RM95, because otherwise the definition would be circular: the level of the anonymous type is that of the view designated by the actual, which is that of the access type.

Discussion: A deeper accessibility level implies a shorter maximum lifetime. Hence, when a rule requires X to have a level that is “not deeper than” Y’s level, this requires that X has a lifetime at least as long as Y. (We say “maximum lifetime” here, because the accessibility level really represents an upper bound on the lifetime; an object created by an allocator can have its lifetime prematurely ended by an instance of Unchecked_Deallocation.)

Package elaborations are not masters, and are therefore invisible to the accessibility rules: an object declared immediately within a package has the same accessibility level as an object declared immediately within the declarative region containing the package. This is true even in the body of a package; it jibes with the fact that objects declared in a package_body live as long as objects declared outside the package, even though the body objects are not visible outside the package.

Note that the level of the view denoted by X.all can be different from the level of the object denoted by X.all. The former is determined by the type of X; the latter is determined either by the type of the allocator, or by the master in which the object was declared. The former is used in several Legality Rules and run-time checks; the latter is used to define when X.all gets finalized. The level of a view reflects what we can conservatively “know” about the object of that view; for example, due to type_conversions, an access value might designate an object that was allocated by an allocator for a different access type.

Similarly, the level of the view denoted by X.all.Comp can be different from the level of the object denoted by X.all.Comp.

If Y is statically deeper than X, this implies that Y will be (dynamically) deeper than X in all possible executions.

Most accessibility checking is done at compile time; the rules are stated in terms of “statically deeper than”. The exceptions are:

- Checks involving access parameters of an access-to-object type. The fact that “statically deeper than” is not defined for the anonymous access type of an access parameter implies that any rule saying “shall not be statically deeper than” does not apply to such a type, nor to anything defined to have “the same” level as such a type.
• [AI05-0082-1] Checks involving generic formal types and their descendants. This is because the actual type can be more or less deeply nested than the generic unit. Note that this only applies to the generic unit itself, and not to the instance. Any static checks needed in the instance will be performed. Any other checks (such as those in the generic body) will require a run-time check of some sort (although implementations that macro-expand generics can determine the result of the check when the generic is expanded).

• [AI05-0082-1] Checks involving other entities and views within generic packages. This is because an instantiation can be at a level that is more deeply nested than the generic package itself. In implementations that use a macro-expansion model of generics, these violations can be detected at macro-expansion time. For implementations that share generics, run-time code is needed to detect the error.

• [AI95-00318-02] {AI95-00344-01} {AI95-00416-01} Checks during function return and allocators, for nested type extensions and access discriminants.

• [AI95-0005-1] Note that run-time checks are not required for access discriminants (except during function returns and allocators), because their accessibility is determined statically by the accessibility level of the enclosing object.

• [AI95-0005-1] The accessibility level of the result object of a function reflects the time when that object will be finalized; we don't allow pointers to the object to survive beyond that time.

We sometimes use the terms “accessible” and “inaccessible” to mean that something has an accessibility level that is not deeper, or deeper, respectively, than something else.

Implementation Note: [AI95-00318-02] {AI95-00344-01} {AI95-00416-01} If an accessibility Legality Rule is satisfied, then the corresponding run-time check (if any) cannot fail (and a reasonable implementation will not generate any checking code) unless one of the cases requiring run-time checks mentioned previously is involved.

Accessibility levels are defined in terms of the relations “the same as” and “deeper than”. To make the discussion more concrete, we can assign actual numbers to each level. Here, we assume that library-level accessibility is level 0, and each level defined as “deeper than” is one level deeper. Thus, a subprogram directly called from the environment task (such as the main subprogram) would be at level 1, and so on.

Accessibility is not enforced at compile time for access parameters of an access-to-object type. The “obvious” implementation of the run-time checks would be inefficient, and would involve distributed overhead; therefore, an efficient method is given below. The “obvious” implementation would be to pass the level of the caller at each subprogram call, task creation, etc. This level would be incremented by 1 for each dynamically nested master. An Accessibility_Check would be implemented as a simple comparison — checking that X is not deeper than Y would involve checking that X <= Y.

A more efficient method is based on passing static nesting levels (within constructs that correspond at run time to masters — packages don't count). Whenever an access parameter is passed, an implicit extra parameter is passed with it. The extra parameter represents (in an indirect way) the accessibility level of the anonymous access type, and, therefore, the level of the view denoted by a dereference of the access parameter. This is analogous to the implicit “Constrained” bit associated with certain formal parameters of an unconstrained but definite composite subtype. In this method, we avoid distributed overhead: it is not necessary to pass any extra information to subprograms that have no access parameters. For anything other than an access parameter and its anonymous type, the static nesting level is known at compile time, and is defined analogously to the RM95 definition of accessibility level (e.g. derived access types get their nesting level from their parent). Checking “not deeper than” is a "<=" test on the levels.

For each access parameter, of an access-to-object type, the static depth passed depends on the actual, as follows:

• If the actual is an expression of a named access type, pass the static nesting level of that type.

• If the actual is a reference to the Allocate attribute, pass the static nesting level of the caller, plus one.

• If the actual is a reference to the Unchecked_Access attribute, pass 0 (the library accessibility level).

• If the actual is an access parameter of an access-to-object type, usually just pass along the level passed in. However, if the static nesting level of the formal (access) parameter is greater than the static nesting level of the actual (access) parameter, the level to be passed is the minimum of the static nesting level of the access parameter and the actual level passed in.

For the Accessibility_Check associated with a type_conversion of an access parameter of an access-to-object type of a given subprogram to a named access type, if the target type is statically nested within the subprogram, do nothing; the check can't fail in this case. Otherwise, check that the value passed in is <= the static nesting depth of the target type. The other Accessibility_Checks are handled in a similar manner.

This method, using statically known values most of the time, is efficient, and, more importantly, avoids distributed overhead.
The implementation of accessibility checks for stand-alone objects of anonymous access-to-object types can be similar to that for anonymous access-to-object parameters. A static level suffices; it can be calculated using rules similar to those previously described for access parameters.

One important difference between the stand-alone access variables and access parameters is that one can assign a local access parameter to a more global stand-alone access variable. Similarly, one can assign a more global access parameter to a more local stand-alone access variable.

For these cases, it is important to note that the “correct” static accessibility level for an access parameter assigned to a stand-alone access object is the minimum of the passed in level and the static accessibility level of the stand-alone object itself. This is true since the static accessibility level passed in might be deeper than that of the stand-alone object, but the dynamic accessibility of the passed in object clearly must be shallower than the stand-alone object (whatever is passed in must live at least as long as the subprogram call). We do not need to keep a more local static level as accesses to objects statically deeper than the stand-alone object cannot be stored into the stand-alone object.

| Discussion: Examples of accessibility: |

The above illegal statements are illegal because the accessibility level of X and Y are statically deeper than the accessibility level of A0. In every possible execution of any program including this library unit, if P is called, the accessibility level of X will be (dynamically) deeper than that of A0. Note that the accessibility levels of X and Y are the same.

Here’s an example involving access parameters of an access-to-object type:

```ada
package body Lib_Unit is
  type T is tagged ...;
  type A0 is access all T;
  Global: A0 := ...;
  procedure P(X: in out T) is
    Y: aliased T;
    type A1 is access all T;
    Ptr0: A0 := Global; -- OK.
    Ptr1: A1 := X'Access; -- OK.
  begin
    Ptr1 := Y'Access; -- OK.
    Ptr0 := A0(Ptr1); -- Illegal type conversion!
    Ptr0 := X'Access; -- Illegal reference to Access attribute!
    Ptr0 := Y'Access; -- Illegal reference to Access attribute!
    Global := Ptr0; -- OK.
  end P;
end Lib_Unit;
```

The run-time Accessibility_Check at (1) can never fail, and no code should be generated to check it. The check at (2) will fail when called from (3), but not when called from (4).

Within a type_declaration, the rules are checked in an assume-the-worst manner. For example:
package P is
  type Int_Ptr is access all Integer;
  type Rec(D: access Integer) is limited private;
private
  type Rec_Ptr is access all Rec;
  function P(X: Rec_Ptr) return Boolean;
  function G(X: access Rec) return Boolean;
  type Rec(D: access Integer) is
    limited record
      C1: Int_Ptr := Int_Ptr(D); -- Illegal!
      C2: Rec_Ptr := Rec'Access; -- Illegal!
      C3: Boolean := F(Rec'Access); -- Illegal!
      C4: Boolean := G(Rec'Access);
    end record;
end P;

C1, C2, and C3 are all illegal, because one might declare an object of type Rec at a more deeply nested place than the declaration of the type. C4 is legal, but the accessibility level of the object will be passed to function G, and constraint checks within G will prevent it from doing any evil deeds.

Note that we cannot defer the checks on C1, C2, and C3 until compile-time of the object creation, because that would cause violation of the privacy of private parts. Furthermore, the problems might occur within a task or protected body, which the compiler can't see while compiling an object creation.

The following attribute is defined for a prefix X that denotes an aliased view of an object:

X'Access {8652/0010} {AI95-00127-01} X'Access yields an access value that designates the object denoted by X. The type of X'Access is an access-to-object type, as determined by the expected type. The expected type shall be a general access type. X shall denote an aliased view of an object[, including possibly the current instance (see 8.6) of a limited type within its definition, or a formal parameter or generic formal object of a tagged type]. The view denoted by the prefix X shall satisfy the following additional requirements, presuming the expected type for X'Access is the general access type A with designated type D:

• If A is an access-to-variable type, then the view shall be a variable; [on the other hand, if A is an access-to-constant type, the view may be either a constant or a variable.]

Discussion: The current instance of a limited type is considered a variable.

• {AI95-00363-01} {AI05-0008-1} {AI05-0041-1} The view shall not be a subcomponent that depends on discriminants of an object unless the object is known to be constrained[4] a variable whose nominal subtype is unconstrained, unless this subtype is indefinite, or the variable is constrained by its initial value aliased.

Discussion: This restriction is intended to be similar to the restriction on renaming discriminant-dependent subcomponents.

Reason: This prevents references to subcomponents that might disappear or move or change constraints after creating the reference.

Implementation Note: There was some thought to making this restriction more stringent, roughly: "X shall not denote a subcomponent of a variable with discriminant-dependent subcomponents, if the nominal subtype of the variable is an unconstrained definite subtype." This was because in some implementations, it is not just the discriminant-dependent subcomponents that might move as the result of an assignment that changed the discriminants of the enclosing object. However, it was decided not to make this change because a reasonable implementation strategy was identified to avoid such problems, as follows:

• Place non-discriminant-dependent components with any aliased parts at offsets preceding any discriminant-dependent components in a discriminated record type with defaulted discriminants.

• Preallocate the maximum space for unconstrained discriminated variables with aliased subcomponents, rather than allocating the initial size and moving them to a larger (heap-resident) place if they grow as the result of an assignment.

Note that for objects of a by-reference type, it is not an error for a programmer to take advantage of the fact that such objects are passed by reference. Therefore, the above approach is also necessary for discriminated record types with components of a by-reference type.
To make the above strategy work, it is important that a component of a derived type is defined to be discriminant-dependent if it is inherited and the parent subtype constraint is defined in terms of a discriminant of the derived type (see 3.7).

- \{8652/0010\}  \{AI95-00127-01\}  \{AI95-00363-01\} If \(A\) is a named access type and \(D\) is a tagged type, the designated type of \(A\) is tagged, then the type of the view shall be covered by \(D\); the designated type; if \(A\) is anonymous and \(D\) is tagged, then the type of the view shall be either \(D\) Class or a type covered by \(D\); if \(D\) is untagged, \(A\)'s designated type is not tagged, then the type of the view shall be \(D\); the same, and either \(A\)'s designated subtype shall either statically match the nominal subtype of the view or be; or the designated subtype shall be discriminated and unconstrained.

- \{AI95-00363-01\} the designated subtype of \(A\) shall statically match the nominal subtype of the view; or

- \{AI95-00363-01\} \{AI05-0041-1\} \(D\) shall be discriminated in its full view and unconstrained in any partial view, and the designated subtype of \(A\) shall be unconstrained. For the purposes of determining within a generic body whether \(D\) is unconstrained in any partial view, a discriminated subtype is considered to have a constrained partial view if it is a descendant of an untagged generic formal private or derived type.

**Implementation Note:** This ensures that the dope for an aliased array object can always be stored contiguous with it, but need not be if its nominal subtype is constrained.

**Ramification:** \{8652/0010\}  \{AI95-00127-01\} An access attribute can be used as the controlling operand in a dispatching call; see 3.9.2.

\{AI95-00363-01\} This does not require that types have a partial view in order to allow an access attribute of an unconstrained discriminated object, only that any partial view that does exist is unconstrained.

- \{AI05-0041-1\} The accessibility level of the view shall not be statically deeper than that of the access type \(A\). In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

**Ramification:** In an instance body, a run-time check applies.

\{AI95-00230-01\} If \(A\) is an anonymous access-to-object type of an access parameter type, then the view can never have a deeper accessibility level than \(A\). The same is true for an anonymous access-to-object type of an access discriminant, except when \(X'\text{Access}\) is used to initialize an access discriminant of an object created by an allocator. The latter case is illegal if the accessibility level of \(X\) is statically deeper than that of the access type of the allocator; a run-time check is needed in the case where the initial value comes from an access parameter. Other anonymous access-to-object types have "normal" accessibility checks.

\{AI05-0041-1\} In addition to the places where Legality Rules normally apply (see 12.3), these requirements apply also in the private part of an instance of a generic unit.

A check is made that the accessibility level of \(X\) is not deeper than that of the access type \(A\). If this check fails, Program_Error is raised.

**Ramification:** The check is needed for access parameters of an access-to-object type and in instance bodies.

\{AI05-0024-1\} Because there are no access parameters permitted for task entries, the accessibility levels are always comparable. We would have to switch to the terminology used in 4.8 and 6.5 based on inclusion within masters if we relax this restriction. That might introduce unacceptable distributed overhead.

**Implementation Note:** \{AI05-0148-1\} This check requires that some indication of lifetime is passed as an implicit parameter along with access parameters of an access-to-object type. A similar indication is required for stand-alone objects of anonymous access-to-object types. No such requirement applies to other anonymous access types, since the checks associated with them are all compile-time checks.

If the nominal subtype of \(X\) does not statically match the designated subtype of \(A\), a view conversion of \(X\) to the designated subtype is evaluated (which might raise Constraint_Error — see 4.6) and the value of \(X'\text{Access}\) designates that view.

The following attribute is defined for a prefix \(P\) that denotes a subprogram:
32.3 P'Access \{AI95-00229-01\} \{AI95-00254-01\} \{AI05-0239-1\} P'Access yields an access value that designates the subprogram denoted by P. The type of P'Access is an access-to-subprogram type (S), as determined by the expected type. The accessibility level of P shall not be statically deeper than that of S. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. The profile of P shall be subtype conformant with the designated profile of S, and shall not be Intrinsic. If the subprogram denoted by P is declared within a generic unit, and the expression P'Access occurs within the body of that generic unit or within the body of a generic unit declared within the declarative region of the generic unit, then the ultimate ancestor of S shall be either a nonformal type declared within the generic unit or an anonymous access type of an access parameter body. S shall be declared within the generic body.

Discussion: \{AI95-00229-01\} The part about generic bodies is worded in terms of the denoted subprogram, not the denoted view; this implies that renaming is invisible to this part of the rule. “Declared within the declarative region of the generic” is referring to child and nested generic units. This rule is partly to prevent contract model problems with respect to the accessibility rules, and partly to ease shared-generic-body implementations, in which a subprogram declared in an instance needs to have a different calling convention from other subprograms with the same profile.

Overload resolution ensures only that the profile is type conformant. This rule specifies that subtype conformance is required (which also requires matching calling conventions). P cannot denote an entry because access-to-subprogram types never have the entry calling convention. P cannot denote an enumeration literal or an attribute function because these have intrinsic calling conventions.

Legality Rules

32.1/3 \{AI05-0188-1\} An expression is said to have distributed accessibility if it is

32.2/3

- a conditional_expression (see 4.5.7); or

32.3/3

- a view conversion, qualified expression, or parenthesized expression whose operand has distributed accessibility.

32.4/3 \{AI05-0188-1\} The statically deeper relationship does not apply to the accessibility level of an expression having distributed accessibility: that is, such an accessibility level is not considered to be statically deeper, nor statically shallower, than any other.

32.5/3 \{AI05-0188-1\} Any static accessibility requirement that is imposed on an expression that has distributed accessibility (or on its type) is instead imposed on the dependent expressions of the underlying conditional_expression. This rule is applied recursively if a dependent expression also has distributed accessibility.

Discussion: This means that any Legality Rule requiring that the accessibility level of an expression (or that of the type of an expression) shall or shall not be statically deeper than some other level also applies, in the case where the expression has distributed accessibility, to each dependent_expression of the underlying conditional_expression.

NOTES

88 The Unchecked_Access attribute yields the same result as the Access attribute for objects, but has fewer restrictions (see 13.10). There are other predefined operations that yield access values: an allocator can be used to create an object, and return an access value that designates it (see 4.8); evaluating the literal null yields a null access value that designates no entity at all (see 4.2).

89 \{AI95-00230-01\} The predefined operations of an access type also include the assignment operation, qualification, and membership tests. Explicit conversion is allowed between general access types with matching designated subtypes; explicit conversion is allowed between access-to-subprogram types with subtype conformant profiles (see 4.6). Named access types have predefined equality operators; anonymous access types do not, but they can use the predefined equality operators for universal access (see 4.5.2).

34.2/3

Reason: \{AI95-00230-01\} Anonymous access types can use the universal access equality operators declared in Standard, while named access types cannot for compatibility reasons. By not having equality operators for anonymous access types, we eliminate the need to specify exactly where the predefined operators for anonymous access types would be defined, as well as the need for an implementer to insert an implicit declaration for "=", etc. at the appropriate place in their symbol table. Note that "=", "Access", and "all" are defined, and "=" is defined though useless since all
instances are constant. The literal null is also defined for the purposes of overload resolution, but is disallowed by a
Legality Rule of this subclause.

90 The object or subprogram designated by an access value can be named with a dereference, either an explicit_dereference
or an implicit_dereference. See 4.1.

Proof: See 3.9.2.

91 The object or subprogram designated by an access value can be named with a dereference, either an explicit_dereference
or an implicit_dereference. See 4.1.

Proof: See 3.9.2.

91 A call through the dereference of an access-to-subprogram value is never a dispatching call.

Proof: See 3.9.2.

92 {AI95-00254-01} The accessibility rules imply that it is not possible to use the Access attribute for subprograms and
parameters of an anonymous access-to-subprogram type may together be used to implement “downward closures” — that
is, to pass a more-nested subprogram as a parameter to a less-nested subprogram, as might be appropriate for example
for an iterator abstraction or numerical integration. Downward closures can also be implemented using generic formal
subprograms (see 12.6). Note that Unchecked_Access is not allowed for subprograms.

93 Note that using an access-to-class-wide tagged type with a dispatching operation is a potentially more structured
alternative to using an access-to-subprogram type.

94 An implementation may consider two access-to-subprogram values to be unequal, even though they designate the same
subprogram. This might be because one points directly to the subprogram, while the other points to a special prologue that
performs an Elaboration_Check and then jumps to the subprogram. See 4.5.2.

Ramification: If equality of access-to-subprogram values is important to the logic of a program, a reference to the
Access attribute of a subprogram should be evaluated only once and stored in a global constant for subsequent use and
equality comparison.

Example of use of the Access attribute:

```
Example of use of the Access attribute:
```

```
Martha : Person_Name := new Person(F);       -- see 3.10.1
Cars   : array (1..2) of aliased Car;

Martha.Vehicle := Cars(1)'Access;
George.Vehicle := Cars(2)'Access;
```

Extensions to Ada 83

We no longer make things like 'Last and "component" (basic) operations of an access type that need to be "declared"
somewhere. Instead, implicit dereference in a prefix takes care of them all. This means that there should never be a
case when X.all'Last is legal while X'Last is not. See AI83-00154.

Incompatibilities With Ada 95

{AI95-00363-01} Aliased variables are not necessarily constrained in Ada 2005 (see 3.6). Therefore, a subcomponent
of an aliased variable may disappear or change shape, and taking 'Access of such a subcomponent thus is illegal, while
the same operation would have been legal in Ada 95. Note that most allocated objects are still constrained by their
initial value (see 4.8), and thus legality of 'Access didn't change for them. For example:

```
type T1 (D1 : Boolean := False) is
  record
    case D1 is
      when False =>
        C1 : aliased Integer;
      when True =>
        null;
    end case;
  end record;

type Acc_Int is access all Integer;

A_T : aliased T1;
```

```
PCE : Acc_Int := A_T.C1'Access; -- Illegal in Ada 2005, legal in Ada 95
A_T := (D1 => True);        -- Raised Constraint_Error in Ada 95, but does not
-- in Ada 2005, so Ptr would become invalid when this
-- is assigned (thus Ptr is illegal).
```

{AI95-00363-01} If a discriminated full type has a partial view (private type) that is constrained, we do not allow
'Access on objects to create a value of an object of an access-to-unconstrained type. Ada 95 allowed this attribute and
various access subtypes, requiring that the heap object be constrained and thus making details of the implementation of
the private type visible to the client of the private type. See 4.8 for more on this topic.

{AI95-00229-01} {AI95-00254-01} Amendment Correction: Taking 'Access of a subprogram declared in a generic
unit in the body of that generic is no longer allowed. Such references can easily be used to create dangling pointers, as
Legality Rules are not rechecked in instance bodies. At the same time, the rules were loosened a bit where that is harmless, and also to allow any routine to be passed to an access parameter of an access-to-subprogram type. The now illegal uses of ‘Access can almost always be moved to the private part of the generic unit, where they are still legal and rechecked upon instantiation for possibly dangling pointers.

Extensions to Ada 95

Corrigendum: Access attributes of objects of class-wide types can be used as the controlling parameter in a dispatching call (see 3.9.2). This was an oversight in Ada 95.

Amendment Correction: The type of the prefix can now be used in resolving Access attributes. This allows more uses of the Access attribute to resolve. For example:

```ada
type Int_Ptr is access all Integer;
type Float_Ptr is access all Float;

function Zap (Val : Int_Ptr) return Float;
function Zap (Val : Float_Ptr) return Float;

Value : aliased Integer := 10;
Result1 : Float := Zap (Value'access); -- Ambiguous in Ada 95; resolves in Ada 2005.
```

This change is upward compatible; any expression that does not resolve by the new rules would have failed a Legality Rule.

Wording Changes from Ada 95

Adjusted the wording to reflect the fact that expressions and function calls are masters.

Defined the accessibility of the various new kinds and uses of anonymous access types.

Incompatibilities With Ada 2005

Correction: Simplified the description of when a discriminant-dependent component is allowed as the prefix of ‘Access to when the object is known to be constrained. This fixes a confusion as to whether a subcomponent of an object that is not certain to be constrained can be used as a prefix of ‘Access. The fix introduces an incompatibility, as the rule did not apply in Ada 95 if the prefix was a constant; but it now applies no matter what kind of object is involved. The incompatibility is not too bad, since most kinds of constants are known to be constrained.

Correction: Corrected the checks for the constrainedness of the prefix of the Access attribute so that assume-the-worst is used in generic bodies. This may make some programs illegal, but those programs were at risk having objects disappear while valid access values still pointed at them.

Extensions to Ada 2005

Correction: Eliminated the static accessibility definition for generic formal types, as the actual can be more or less nested than the generic itself. This allows programs that were illegal for Ada 95 and for Ada 2005.

Eliminate the static accessibility definition for stand-alone objects of anonymous access-to-object types. This allows such objects to be used as temporaries without causing accessibility problems.

Wording Changes from Ada 2005

Corrected the rules so that the accessibility of the object designated by an access object is that of the access type, even when no dereference is given. The accessibility was not specified in the past. This correction applies to both Ada 95 and Ada 2005.

Corrected accessibility rules for access discriminants so that no cases are omitted.

Corrected accessibility rules for anonymous access return types and access discriminants in return statements.

Changed coextension rules so that coextensions that belong to an anonymous object are transferred to the ultimate object.

Defined the accessibility of explicitly aliased parameters (see 6.1) and conditional expressions (see 4.5.7).

Defined the term “master of the call” to simplify other wording, especially that for the accessibility checks associated with return statements and explicitly aliased parameters.

Defined the (omitted) accessibility level of null values when those are passed as the actual of an access-to-object parameter.
3.11 Declarative Parts

[A declarative_part contains declarative_items (possibly none).]

Syntax

declarative_part ::= \{declarative_item\}

declarative_item ::= basic_declarative_item | body

{8652/0009} \{AI95-00137-01\} basic_declarative_item ::= basic_declaration | aspect_clause | representation_clause | use_clause

body ::= proper_body | body_stub

proper_body ::= subprogram_body | package_body | task_body | protected_body

Static Semantics

\{AI95-00420-01\} The list of declarative_items of a declarative_part is called the declaration list of the declarative_part.

Dynamic Semantics

The elaboration of a declarative_part consists of the elaboration of the declarative_items, if any, in the order in which they are given in the declarative_part.

An elaborable construct is in the elaborated state after the normal completion of its elaboration. Prior to that, it is not yet elaborated.

Ramification: The elaborated state is only important for bodies; certain uses of a body raise an exception if the body is not yet elaborated.

Note that "prior" implies before the start of elaboration, as well as during elaboration.

The use of the term "normal completion" implies that if the elaboration propagates an exception or is aborted, the declaration is not elaborated. RM83 missed the aborted case.

For a construct that attempts to use a body, a check (Elaboration_Check) is performed, as follows:

- \{8652/0014\} \{AI95-00064-01\} For a call to a (non-protected) subprogram that has an explicit body, a check is made that the body subprogram_body is already elaborated. This check and the evaluations of any actual parameters of the call are done in an arbitrary order.

Discussion: AI83-00180 specifies that there is no elaboration check for a subprogram defined by a pragma Interface (or equivalently, pragma Import). AI83-00430 specifies that there is no elaboration check for an enumeration literal. AI83-00406 specifies that the evaluation of parameters and the elaboration check occur in an arbitrary order. AI83-00406 applies to generic instantiation as well (see below).

\{8652/0014\} \{AI95-00064-01\} \{AI05-0177-1\} A subprogram can be completed by a renaming-as-body, a null_procedure_declaration, or an expression_function_declaration, and we need to make an elaboration check on such a body, so we use "body" rather than subprogram_body above.

- \{AI05-0229-1\} For a call to a protected operation of a protected type (that has a body — no check is performed if a pragma Import applies to the protected type is imported — see B.1), a check is made that the protected_body is already elaborated. This check and the evaluations of any actual parameters of the call are done in an arbitrary order.

Discussion: A protected type has only one elaboration “bit,” rather than one for each operation, because one call may result in evaluating the barriers of other entries, and because there are no elaborable declarations between the bodies of the operations. In fact, the elaboration of a protected_body does not elaborate the enclosed bodies, since they are not considered independently elaborable.
Note that there is no elaboration check when calling a task entry. Task entry calls are permitted even before the associated task_body has been seen. Such calls are simply queued until the task is activated and reaches a corresponding accept_statement. We considered a similar rule for protected entries — simply queuing all calls until the protected_body was seen, but felt it was not worth the possible implementation overhead, particularly given that there might be multiple instances of the protected type.

• For the activation of a task, a check is made by the activator that the task_body is already elaborated. If two or more tasks are being activated together (see 9.2), as the result of the elaboration of a declarative_part or the initialization for the object created by an allocator, this check is done for all of them before activating any of them.

Reason: As specified by AI83-00149, the check is done by the activator, rather than by the task itself. If it were done by the task itself, it would be turned into a Tasking_Error in the activator, and the other tasks would still be activated.

• For the instantiation of a generic unit that has a body, a check is made that this body is already elaborated. This check and the evaluation of any explicit_generic_actual_parameters of the instantiation are done in an arbitrary order.

The exception Program_Error is raised if any of these checks fails.

Extensions to Ada 83

{AI95-00114-01} The syntax for declarative_part is modified to remove the ordering restrictions of Ada 83; that is, the distinction between basic_declarative_items and later_declarative_items within declarative_parts is removed. This means that things like use_clauses and object_declaration_variable_declarations can be freely intermixed with things like bodies.

The syntax rule for proper_body now allows a protected_body, and the rules for elaboration checks now cover calls on protected operations.

Wording Changes from Ada 83

The syntax rule for later_declarative_item is removed; the syntax rule for declarative_item is new.

RM83 defines “elaborated” and “not yet elaborated” for declarative_items here, and for other things in 3.1, “Declarations”. That's no longer necessary, since these terms are fully defined in 3.1.

In RM83, all uses of declarative_part are optional (except for the one in block_statement with a declare) which is sort of strange, since a declarative_part can be empty, according to the syntax. That is, declarative_parts are sort of “doubly optional”. In Ada 95, these declarative_parts are always required (but can still be empty). To simplify description, we go further and say (see 5.6, “Block Statements”) that a block_statement without an explicit declarative_part is equivalent to one with an empty one.

Wording Changes from Ada 95

{8652/0009} {AI95-00137-01} Corrigendum: Changed representation clauses to aspect clauses to reflect that they are used for more than just representation.

{8652/0014} {AI95-00064-01} Corrigendum: Clarified that the elaboration check applies to all kinds of subprogram bodies.

{AI95-00420-01} Defined “declaration list” to avoid confusion for various rules. Other kinds of declaration list are defined elsewhere.

3.11.1 Completions of Declarations

Declarations sometimes come in two parts. A declaration that requires a second part is said to require completion. The second part is called the completion of the declaration (and of the entity declared), and is either another declaration, a body, or a pragma. A body is a body, an entry body, a null procedure declaration or an expression function declaration that completes another declaration, or a renaming-as-body (see 8.5.4).

Discussion: Throughout the RM95, there are rules about completions that define the following:

• Which declarations require a corresponding completion.

• Which constructs can only serve as the completion of a declaration.
Where the completion of a declaration is allowed to be.

What kinds of completions are allowed to correspond to each kind of declaration that allows one.

Don't confuse this compile-time concept with the run-time concept of completion defined in 7.6.1.

Note that the declaration of a private type (if limited) can be completed with the declaration of a task type, which is then completed with a body. Thus, a declaration can actually come in three parts.

{AI95-00217-06} {AI05-0162-1} An incomplete type (whether declared in the limited view of a package or not) may be completed by a private type declaration. In Ada 2005 the limited view of the package contains an incomplete view of the private type, so we can in fact have four parts now.

{AI05-0229-1} In Ada 2012, there are no language-defined pragmas that act as completions. Pragmas Import (which is obsolescent) has the effect of setting Aspect Import to True; such an aspect makes giving a completion illegal. The wording that allows pragmas as completions was left as it is harmless and appears in many places in this Standard.

Name Resolution Rules

A construct that can be a completion is interpreted as the completion of a prior declaration only if:

- The declaration and the completion occur immediately within the same declarative region;
- The defining name or defining_program_unit_name in the completion is the same as in the declaration, or in the case of a pragma, the pragma applies to the declaration;
- If the declaration is overloadable, then the completion either has a type-conformant profile, or is a pragma.

Legality Rules

{AI05-0229-1} An implicit declaration shall not have a completion. For any explicit declaration that is specified to require completion, there shall be a corresponding explicit completion unless the declared entity is imported (see B.1).

To be honest: {AI95-00217-06} The implicit declarations occurring in a limited view do have a completion (the explicit declaration occurring in the full view) but that's a special case, since the implicit declarations are actually built from the explicit ones. So they do not require a completion, they have one by fiat.

Discussion: {AI05-0299-1} The implicit declarations of predefined operators are not allowed to have a completion. Enumeration literals, although they are subprograms, are not allowed to have a corresponding subprogram_body. That's because the completion rules are described in terms of constructs (subprogram_declarations) and not entities (subprograms). When a completion is required, it has to be explicit: the implicit null package_body that Clause 7 talks about cannot serve as the completion of a package_declaration if a completion is required.

At most one completion is allowed for a given declaration. Additional requirements on completions appear where each kind of completion is defined.

Ramification: A subunit is not a completion; the stub is.

If the completion of a declaration is also a declaration, then that declaration might have a completion, too. For example, a limited private type can be completed with a task type, which can then be completed with a task body. This is not a violation of the “at most one completion” rule.

A type is completely defined at a place that is after its full type definition (if it has one) and after all of its subcomponent types are completely defined. A type shall be completely defined before it is frozen (see 13.14 and 7.3).

Reason: Index types are always completely defined — no need to mention them. There is no way for a completely defined type to depend on the value of a (still) deferred constant.

NOTES

95 {AI05-0229-1} Completions are in principle allowed for any kind of explicit declaration. However, for some kinds of declaration, the only allowed completion is an implementation-defined pragma pragma_import, and implementations are not required to have any such pragmas support pragma Import for every kind of entity.

This paragraph was deleted.

Discussion: {AI05-0299-1} In fact, we expect that implementations will not support pragma Import of things like types — it’s hard to even define the semantics of what it would mean. Therefore, in practice, not every explicit declaration can have a completion. In any case, if an implementation chooses to support pragma Import
for, say, types, it can place whatever restrictions on the feature it wants to. For example, it might want the pragma to be a freezing point for the type.

There are rules that prevent premature uses of declarations that have a corresponding completion. The Elaboration_Checks of 3.11 prevent such uses at run time for subprograms, protected operations, tasks, and generic units. The rules of 13.14, “Freezing Rules” prevent, at compile time, premature uses of other entities such as private types and deferred constants.

### Wording Changes from Ada 83

This subclause is new. It is intended to cover all kinds of completions of declarations, be they a body for a spec, a full type for an incomplete or private type, a full constant declaration for a deferred constant declaration, or a pragma Import for any kind of entity.

### Wording Changes from Ada 95

{8652/0014} {AI95-00064-01} **Corrigendum:** Added a definition of `body`, which is different than `body` or `body`.

### Wording Changes from Ada 2005

{AI95-0177-1} **Added null procedures and expression functions that are completions to the definition of `body`.**
4 Names and Expressions

{AI05-0299-1} [The rules applicable to the different forms of name and expression, and to their evaluation, are given in this clause section.]

4.1 Names

{Names can denote declared entities, whether declared explicitly or implicitly (see 3.1). Names can also denote objects or subprograms designated by access values; the results of type conversions or function calls; subcomponents and slices of objects and values; protected subprograms, single entries, entry families, and entries in families of entries. Finally, names can denote attributes of any of the foregoing.]}

Syntax

{AI05-0003-1} {AI05-0139-2} name ::= 2/3
direct_name | explicit_dereference
| indexed_component | slice
| selected_component | attribute_reference
| type_conversion | function_call
| character_literal | qualified_expression
| generalized_reference | generalized_indexing

direct_name ::= identifier | operator_symbol

Discussion: {AI95-00114-01} character_literal is no longer a direct_name. character_literals are usable even when the corresponding enumeration type declaration is not visible. See 4.2.

prefix ::= name | implicit_dereference

explicit_dereference ::= name.all

implicit_dereference ::= name

{AI05-0004-1} [Certain forms of name (indexed_components, selected_components, slices, and attribute_references) include a prefix that is either itself a name that denotes some related entity, or an implicit_dereference of an access value that designates some related entity.]

Name Resolution Rules

The name in a dereference (either an implicit_dereference or an explicit_dereference) is expected to be of any access type.

Static Semantics

{AI05-0008-1} If the type of the name in a dereference is some access-to-object type T, then the dereference denotes a view of an object, the nominal subtype of the view being the designated subtype of T. If the designated subtype has unconstrained discriminants, the (actual) subtype of the view is constrained by the values of the discriminants of the designated object, except when there is a partial view of the type of the designated subtype that does not have discriminants, in which case the dereference is not constrained by its discriminant values.

Ramification: If the value of the name is the result of an access type conversion, the dereference denotes a view created as part of the conversion. The nominal subtype of the view is not necessarily the same as that used to create the designated object. See 4.6.

To be honest: We sometimes refer to the nominal subtype of a particular kind of name rather than the nominal subtype of the view denoted by the name (presuming the name denotes a view of an object). These two uses of nominal subtype are intended to mean the same thing.
4.1 Names

Reason: {AI05-0008-1} The last sentence was not present in Ada 95; it is necessary in Ada 2005 because general access types can designate unconstrained objects, which was not possible in Ada 95. Thus, the rules that had this effect in Ada 95 (the object being constrained by its initial value) don't work in Ada 2005 and we have to say this explicitly.

{AI05-0008-1} The “except” part of the last sentence prevents privacy “breaking”, so that if a private type has discriminants only in the full view, they don't interfere with freely interassigning values between objects of the type, even when the objects live in the heap.

Implementation Note: {AI05-0008-1} Since we don't depend on whether the designated object is constrained, it is not necessary to include a constrained bit in every object that could be designated by a general access type.

If the type of the name in a dereference is some access-to-subprogram type S, then the dereference denotes a view of a subprogram, the profile of the view being the designated profile of S.

Ramification: This means that the formal parameter names and default expressions to be used in a call whose name or prefix is a dereference are those of the designated profile, which need not be the same as those of the subprogram designated by the access value, since ‘Access requires only subtype conformance, not full conformance.

\[\text{Dynamic Semantics}\]

{AI95-00415-01} The evaluation of a name determines the entity denoted by the name name. This evaluation has no other effect for a name that is a direct_name or a character_literal.

[The evaluation of a name that has a prefix includes the evaluation of the prefix.] The evaluation of a prefix consists of the evaluation of the name or the implicit_dereference. The prefix denotes the entity denoted by the name or the implicit_dereference.

The evaluation of a dereference consists of the evaluation of the name and the determination of the object or subprogram that is designated by the value of the name. A check is made that the value of the name is not the null access value. Constraint_Error is raised if this check fails. The dereference denotes the object or subprogram designated by the value of the name.

Examples of direct names:

- Pi -- the direct name of a number (see 3.3.2)
- Limit -- the direct name of a constant (see 3.3.1)
- Count -- the direct name of a scalar variable (see 3.3.1)
- Board -- the direct name of an array variable (see 3.6.1)
- Matrix -- the direct name of a type (see 3.6)
- Random -- the direct name of a function (see 6.1)
- Error -- the direct name of an exception (see 11.1)

Examples of dereferences:

- Next_Car.all -- explicit dereference denoting the object designated by
- -- the access variable Next.Car (see 3.10.1)
- Next.Car.Owner -- selected component with implicit dereference;
- -- same as Next.Car.all.Owner

Extensions to Ada 83

Type conversions and function calls are now considered names that denote the result of the operation. In the case of a type conversion used as an actual parameter or that is of a tagged type, the type conversion is considered a variable if the operand is a variable. This simplifies the description of "parameters of the form of a type conversion" as well as better supporting an important OOP paradigm that requires the combination of a conversion from a class-wide type to some specific type followed immediately by component selection. Function calls are considered names so that a type conversion of a function call and the function call itself are treated equivalently in the grammar. A function call is considered the name of a constant, and can be used anywhere such a name is permitted. See 6.5.

Type conversions of a tagged type are permitted anywhere their operand is permitted. That is, if the operand is a variable, then the type conversion can appear on the left-hand side of an assignment_statement. If the operand is an object, then the type conversion can appear in an object renaming or as a prefix. See 4.6.
4.1.1 Indexed Components

[An indexed_component denotes either a component of an array or an entry in a family of entries.]

Syntax

\[
\text{indexed_component ::= prefix(expression}, \, \text{expression})
\]

Name Resolution Rules

The prefix of an indexed_component with a given number of expressions shall resolve to denote an array (after any implicit dereference) with the corresponding number of index positions, or shall resolve to denote an entry family of a task or protected object (in which case there shall be only one expression).

The expected type for each expression is the corresponding index type.

Static Semantics

When the prefix denotes an array, the indexed_component denotes the component of the array with the specified index value(s). The nominal subtype of the indexed_component is the component subtype of the array type.
Ramification: {AI95-00363-01} In the case of an array whose components are aliased, and of an unconstrained discriminated subtype, the components are constrained even though their nominal subtype is unconstrained. (This is because all aliased discriminated objects are constrained. See 3.10.2.) In all other cases, an array component is constrained if and only if its nominal subtype is constrained.

When the prefix denotes an entry family, the indexed_component denotes the individual entry of the entry family with the specified index value.

Dynamic Semantics

For the evaluation of an indexed_component, the prefix and the expressions are evaluated in an arbitrary order. The value of each expression is converted to the corresponding index type. A check is made that each index value belongs to the corresponding index range of the array or entry family denoted by the prefix. Constraint_Error is raised if this check fails.

Examples of indexed components:

- My_Schedule(Sat) -- a component of a one-dimensional array (see 3.6.1)
- Page(10) -- a component of a one-dimensional array (see 3.6)
- Board(M, J + 1) -- a component of a two-dimensional array (see 3.6.1)
- Page(10)(20) -- a component of a component (see 3.6)
- Request(Medium) -- an entry in a family of entries (see 9.1)
- Next_Frame(L)(M, N) -- a component of a function call (see 6.1)

NOTES

1 Notes on the examples: Distinct notations are used for components of multidimensional arrays (such as Board) and arrays of arrays (such as Page). The components of an array of arrays are arrays and can therefore be indexed. Thus Page(10)(20) denotes the 20th component of Page(10). In the last example Next_Frame(L) is a function call returning an access value that designates a two-dimensional array.

4.1.2 Slices

A slice denotes a one-dimensional array formed by a sequence of consecutive components of a one-dimensional array. A slice of a variable is a variable; a slice of a constant is a constant.] a slice of a value is a value.

Syntax

- slice ::= prefix(discrete_range)

Name Resolution Rules

The prefix of a slice shall resolve to denote a one-dimensional array (after any implicit dereference).

The expected type for the discrete_range of a slice is the index type of the array type.

Static Semantics

A slice denotes a one-dimensional array formed by the sequence of consecutive components of the array denoted by the prefix, corresponding to the range of values of the index given by the discrete_range.

The type of the slice is that of the prefix. Its bounds are those defined by the discrete_range.

Dynamic Semantics

For the evaluation of a slice, the prefix and the discrete_range are evaluated in an arbitrary order. If the slice is not a null slice (a slice where the discrete_range is a null range), then a check is made that the bounds of the discrete_range belong to the index range of the array denoted by the prefix. Constraint_Error is raised if this check fails.
NOTES
2 A slice is not permitted as the prefix of an Access attribute_reference, even if the components or the array as a whole are
aliased. See 3.10.2.

Proof: Slices are not aliased, by 3.10, “Access Types”.

Reason: This is to ease implementation of general-access-to-array. If slices were aliased, implementations would need
to store array dope with the access values, which is not always desirable given access-to-incomplete types completed
in a package body.

3 For a one-dimensional array A, the slice A(N .. N) denotes an array that has only one component; its type is the type of
A. On the other hand, A(N) denotes a component of the array A and has the corresponding component type.

Examples

Examples of slices:

Stars(1 .. 15) -- a slice of 15 characters (see 3.6.3)
Page(10 .. 10 + Size) -- a slice of 1 + Size components (see 3.6)
Page(L)(A .. B) -- a slice of the array Page(L) (see 3.6)
Stars(1 .. 0) -- a null slice (see 3.6.3)
My_Schedule(Weekday) -- bounds given by subtype (see 3.6.1 and 3.5.1)
Stars(5 .. 15)(K) -- same as Stars(K) (see 3.6.3)
-- provided that K is in 5 .. 15

4.1.3 Selected Components

[Selected_components are used to denote components (including discriminants), entries, entry families,
and protected subprograms; they are also used as expanded names as described below. ]

Syntax

selected_component ::= prefix . selector_name

selector_name ::= identifier | character_literal | operator_symbol

Name Resolution Rules

A selected_component is called an expanded name if, according to the visibility rules, at least one
possible interpretation of its prefix denotes a package or an enclosing named construct (directly, not
through a subprogram_renaming_declaration or generic_renaming_declaration).

Discussion: See AI83-00187.

A selected_component that is not an expanded name shall resolve to denote one of the following:

Ramification: If the prefix of a selected_component denotes an enclosing named construct, then the
selected_component is interpreted only as an expanded name, even if the named construct is a function that could be
called without parameters.

• A component [(including a discriminant)]:

The prefix shall resolve to denote an object or value of some non-array composite type (after any
implicit dereference). The selector_name shall resolve to denote a discriminant_specification of
the type, or, unless the type is a protected type, a component_declaration of the type. The
selected_component denotes the corresponding component of the object or value.

Reason: {AI05-0005-1} The components of a protected object cannot be named except by an expanded name, even
from within the corresponding protected body. The protected body cannot reference the--the private
components of some arbitrary object of the protected type; the protected body may reference components of the current
instance only (by an expanded name or a direct_name).

Ramification: Only the discriminants and components visible at the place of the selected_component can be selected,
since a selector_name can only denote declarations that are visible (see 8.3).

• A single entry, an entry family, or a protected subprogram:
The prefix shall resolve to denote an object or value of some task or protected type (after any implicit dereference). The selector_name shall resolve to denote an entry_declaration or subprogram_declaration occurring (implicitly or explicitly) within the visible part of that type. The selected_component denotes the corresponding entry, entry family, or protected subprogram.

**Reason:** This explicitly says “visible part” because even though the body has visibility on the private part, it cannot call the private operations of some arbitrary object of the task or protected type, only those of the current instance (and expanded name notation has to be used for that).

9.a

- **{AI95-00252-01} {AI95-00407-01}** A view of a subprogram whose first formal parameter is of a tagged type or is an access parameter whose designated type is tagged:

9.1/2

**{AI95-00252-01} {AI95-00407-01} {AI05-0090-1}** The prefix (after any implicit dereference) shall resolve to denote an object or value of a specific tagged type \( T \) or class-wide type \( T'\text{Class} \). The selector_name shall resolve to denote a view of a subprogram declared immediately within the declarative region in which an ancestor of the type \( T \) is declared. The first formal parameter of the subprogram shall be of type \( T \), or a class-wide type that covers \( T \), or an access parameter designating one of these types. The designator of the subprogram shall not be the same as that of a component of the tagged type visible at the point of the selected_component. The subprogram shall not be an implicitly declared primitive operation of type \( T \) that overrides an inherited subprogram implemented by an entry or protected subprogram visible at the point of the selected_component. The selected_component denotes a view of this subprogram that omits the first formal parameter. This view is called a prefixed view of the subprogram, and the prefix of the selected_component (after any implicit dereference) is called the prefix of the prefixed view.

9.2/3

**Discussion:** {AI05-0090-1} The part of the rule that excludes a primitive overriding subprogram as a selector applies only to the wrapper subprogram that is implicitly declared to override a subprogram inherited from a synchronized interface that is implemented by an operation of a task or protected type (see 9.1 and 9.4). We don't want calls that use a prefixed view to be ambiguous between the wrapper subprogram and the implementing entry or protected operation. Note that it is illegal to declare an explicit primitive that has a prefixed view that is homographic with one of the type's operations, so in normal cases it isn't possible to have an ambiguity in a prefix call. However, a class-wide operation of an ancestor type that is declared in the same declaration list with the ancestor type is also considered, and that can still make a call ambiguous.

10 An expanded name shall resolve to denote a declaration that occurs immediately within a named declarative region, as follows:

- The prefix shall resolve to denote either a package [(including the current instance of a generic package, or a rename of a package)], or an enclosing named construct.

- The selector_name shall resolve to denote a declaration that occurs immediately within the declarative region of the package or enclosing construct [(the declaration shall be visible at the place of the expanded name — see 8.3)]. The expanded name denotes that declaration.

12.a

**Ramification:** Hence, a library unit or subunit can use an expanded name to refer to the declarations within the private part of its parent unit, as well as to other children that have been mentioned in with_clauses.

If the prefix does not denote a package, then it shall be a direct_name or an expanded name, and it shall resolve to denote a program unit (other than a package), the current instance of a type, a block_statement, a loop_statement, or an accept_statement (in the case of an accept_statement or entry_body, no family index is allowed); the expanded name shall occur within the declarative region of this construct. Further, if this construct is a callable construct and the prefix denotes more than one such enclosing callable construct, then the expanded name is ambiguous, independently of the selector_name.

**Legality Rules**

13.1/2

**{AI95-00252-01} {AI95-00407-01}** For a subprogram whose first parameter is an access parameter, the prefix of any prefixed view shall denote an aliased view of an object.
For a subprogram whose first parameter is of mode **in out** or of an anonymous access-to-variable type, the prefix of any prefixed view shall denote a variable.

**Reason**: We want calls through a prefixed view and through a normal view to have the same legality. Thus, the implicit 'Access in this new notation needs the same legality check that an explicit 'Access would have. Similarly, we need to prohibit the object from being constant if the first parameter of the subprogram is **in out**, because that is (obviously) prohibited for passing a normal parameter.

**Dynamic Semantics**

The evaluation of a **selected_component** includes the evaluation of the prefix.

For a **selected_component** that denotes a component of a variant, a check is made that the values of the discriminants are such that the value or object denoted by the prefix has this component. The exception **Constraint_Error** is raised if this check fails.

**Examples**

**Examples of selected components:**

- **{AI95-00252-01} {AI95-00407-01} Tomorrow.Month** -- a record component (see 3.8)
- **Next.Car.Owner.Age** -- a record component (see 3.10.1)
- **Min_Cell(H).Value** -- a record component of the result (see 6.1)
- **Control.Seize** -- an entry of a protected object (see 9.4)
- **Pool(K).Write** -- an entry of the task Pool(K) (see 9.4)

**Examples of expanded names:**

- **Key_Manager."<"** -- an operator of the visible part of a package (see 7.3.1)
- **Buffer.Pool** -- a variable declared in a function body (see 6.1)
- **Buffer.Read** -- an entry of a protected unit (see 9.11)
- **Swap.Temp** -- a variable declared in a block statement (see 5.6)
- **Standard.Boolean** -- the name of a predefined type (see A.1)

**Extensions to Ada 83**

We now allow an expanded name to use a prefix that denotes a rename of a package, even if the selector is for an entity local to the body or private part of the package, so long as the entity is visible at the place of the reference. This eliminates a preexisting anomaly where references in a package body may refer to declarations of its visible part but not those of its private part or body when the prefix is a rename of the package.

**Wording Changes from Ada 83**

The syntax rule for **selector_name** is new. It is used in places where visibility, but not necessarily direct visibility, is required. See 4.1, “Names” for more information.

The description of dereferencing an access type has been moved to 4.1, “Names”; **name.all** is no longer considered a **selected_component**.

The rules have been restated to be consistent with our new terminology, to accommodate class-wide types, etc.

**Extensions to Ada 95**

**{AI95-00252-01}** The prefixed view notation for tagged objects is new. This provides a similar notation to that used in other popular languages, and also reduces the need for **use clause**s. This is sometimes known as “distinguished receiver notation”.

Given the following definitions for a tagged type **T**:

- **procedure Do_Something (Obj : in out T; Count : in Natural);**
- **procedure Do_Something_Else (Obj : access T; Flag : in Boolean);**
- **My_Object : aliased T;**

the following calls are equivalent:
4.1.3 Selected Components

19.i/2

Do_Something (My_Object, Count => 10);
My_Object.Do_Something (Count => 10);

as are the following calls:

19.j/2

Do_Something_Else (My_Object'Access, Flag => True);
My_Object.Do_Something_Else (Flag => True);

Wording Changes from Ada 2005

{AI05-0090-1} Correction: Corrected the definition of a prefixed view to ignore the implicit subprograms declared for "implemented by" entries and protected subprograms.

4.1.4 Attributes

[An attribute is a characteristic of an entity that can be queried via an attribute_reference or a range_attribute_reference.]

Syntax

attribute_reference ::= prefix'attribute_designator

{AI05-0004-1} attribute_designator ::= identifier((static_expression))
| Access | Delta | Digits | Mod

range_attribute_reference ::= prefix'range_attribute_designator

range_attribute_designator ::= Range[(static_expression)]

Name Resolution Rules

In an attribute_reference, if the attribute_designator is for an attribute defined for (at least some) objects of an access type, then the prefix is never interpreted as an implicit_dereference; otherwise (and for all range_attribute_references), if the type of the name within the prefix is of an access type, the prefix is interpreted as an implicit_dereference. Similarly, if the attribute_designator is for an attribute defined for (at least some) functions, then the prefix is never interpreted as a parameterless function_call; otherwise (and for all range_attribute_references), if the prefix consists of a name that denotes a function, it is interpreted as a parameterless function_call.

Discussion: The first part of this rule is essentially a "preference" against implicit dereference, so that it is possible to ask for, say, 'Size of an access object, without automatically getting the size of the object designated by the access object. This rule applies to 'Access, 'Unchecked_Access, 'Size, and 'Address, and any other attributes that are defined for at least some access objects.

The second part of this rule implies that, for a parameterless function F, F'Address is the address of F, whereas F'Size is the size of the anonymous constant returned by F.

We normally talk in terms of expected type or profile for name resolution rules, but we don't do this for attributes because certain attributes are legal independent of the type or the profile of the prefix.

{AI95-00114-01} Other than the rules given above, the Name Resolution Rules for the prefix of each attribute are defined as Name Resolution Rules for that attribute. If no such rules are defined, then no context at all should be used when resolving the prefix. In particular, any knowledge about the kind of entities required must not be used for resolution unless that is required by Name Resolution Rules. This matters in obscure cases; for instance, given the following declarations:

function Get_It return Integer is ... -- (1)
function Get_It return Some_Record_Type is ... -- (2)

the following attribute_reference cannot be resolved and is illegal:

if Get_It'Valid then

{AI05-0005-1} even though the Valid attribute is only defined for objects of scalar types, and thus cannot be applied to the result of function (2). That information cannot be used to resolve the prefix. The same would be true if (2) had been a procedure; even though the procedure does not denote an object, the attribute_reference is still illegal.
The expression, if any, in an attribute_designator or range_attribute_designator is expected to be of any integer type.

Legality Rules

The expression, if any, in an attribute_designator or range_attribute_designator shall be static.

Static Semantics

{AI05-0006-1} An attribute_reference denotes a value, an object, a subprogram, or some other kind of program entity. For an attribute_reference that denotes a value or an object, if its type is scalar, then its nominal subtype is the base subtype of the type; if its type is tagged, its nominal subtype is the first subtype of the type; otherwise, its nominal subtype is a subtype of the type without any constraint or null_exclusion. Similarly, unless explicitly specified otherwise, for an attribute_reference that denotes a function, when its result type is scalar, its result subtype is the base subtype of the type, when its result type is tagged, the result subtype is the first subtype of the type, and when the result type is some other type, the result subtype is a subtype of the type without any constraint or null_exclusion.

Ramification: The attributes defined by the language are summarized in K.2. Implementations can define additional attributes.

Discussion: {AI05-0006-1} The nominal subtype is primarily a concern when an attribute_reference, or a call on an attribute_reference, is used as the expression of a case statement, due to the full coverage requirement based on the nominal subtype. For nondiscrete cases, we define the nominal subtype mainly for completeness. Implementations may specify otherwise for implementation-defined attribute functions.

The rule is written to match the meaning of the italicized T in the definition of attributes such as Input; see 4.5.1.

To be honest: {AI05-0006-1} We don't worry about the fact that "base subtype" is not explicitly defined for the universal types. Since it is not possible to constrain a universal numeric type, all subtypes are unconstrained, and hence can be considered base subtypes. The wording above could be altered to bypass this issue, but it doesn't seem necessary, since universal integer is handled specially in the rules for case expression full coverage, and we don't allow user-defined functions for attribute functions whose result type is universal.

[A range_attribute_reference X’Range(N) is equivalent to the range X’First(N) .. X’Last(N), except that the prefix is only evaluated once. Similarly, X’Range is equivalent to X’First .. X’Last, except that the prefix is only evaluated once.]

Dynamic Semantics

The evaluation of an attribute_reference (or range_attribute_reference) consists of the evaluation of the prefix.

Implementation Permissions

{8652/0015} {AI95-00093-01} An implementation may provide implementation-defined attributes; the identifier for an implementation-defined attribute shall differ from those of the language-defined attributes unless supplied for compatibility with a previous edition of this International Standard.

Implementation defined: Implementation-defined attributes.

Ramification: They cannot be reserved words because reserved words are not legal identifiers.

The semantics of implementation-defined attributes, and any associated rules, are, of course, implementation defined. For example, the implementation defines whether a given implementation-defined attribute can be used in a static expression.

{8652/0015} {AI95-00093-01} Implementations are allowed to support the Small attribute for floating types, as this was defined in Ada 83, even though the name would conflict with a language-defined attribute.

NOTES
4 Attributes are defined throughout this International Standard, and are summarized in K.2.
5 {AI95-00235} In general, the name in a prefix of an attribute_reference (or a range_attribute_reference) has to be resolved without using any context. However, in the case of the Access attribute, the expected type for the

attribute_reference)

14.a/2

Proof: \{AI95-00235\} In the general case, there is no “expected type” for the prefix of an attribute_reference. In the special case of ‘Access’, there is an “expected type” or “expected profile” for the prefix.

Reason: ‘Access’ is a special case, because without it, it would be very difficult to take ‘Access’ of an overloaded subprogram.

Examples of attributes:

Color'First        -- minimum value of the enumeration type Color (see 3.5.1)
Rainbow'Base'First -- same as Color'First (see 3.5.1)
Real'Digits        -- precision of the type Real (see 3.5.7)
Board'Last(2)      -- upper bound of the second dimension of Board (see 3.6.1)
Board'Range(1)     -- index range of the first dimension of Board (see 3.6.1)
Pool(K)'Terminated -- True if task Pool(K) is terminated (see 9.1)
Date'Size          -- number of bits for records of type Date (see 3.8)
Message'Address    -- address of the record variable Message (see 3.7.1)

Extensions to Ada 83

16.a
We now uniformly treat X'Range as X'First..X'Last, allowing its use with scalar subtypes.

16.b
We allow any integer type in the static_expression of an attribute designator, not just a value of universal_integer. The preference rules ensure upward compatibility.

Wording Changes from Ada 83

16.c
We use the syntactic category attribute_reference rather than simply "attribute" to avoid confusing the name of something with the thing itself.

16.d
The syntax rule for attribute_reference now uses identifier instead of simple_name, because attribute identifiers are not required to follow the normal visibility rules.

16.e
We now separate attribute_reference from range_attribute_reference, and enumerate the reserved words that are legal attribute or range attribute designators. We do this because identifier no longer includes reserved words.

16.f
The Ada 95 name resolution rules are a bit more explicit than in Ada 83. The Ada 83 rule said that the "meaning of the prefix of an attribute must be determinable independently of the attribute designator and independently of the fact that it is the prefix of an attribute." That isn't quite right since the meaning even in Ada 83 embodies whether or not the prefix is interpreted as a parameterless function call, and in Ada 95, it also embodies whether or not the prefix is interpreted as an implicit_dereference. So the attribute designator does make a difference — just not much.

16.g
Note however that if the attribute designator is Access, it makes a big difference in the interpretation of the prefix (see 3.10.2).

Wording Changes from Ada 95

16.h/2
\{8652/0015\} \{AI95-00093-01\} Corrigendum: The wording was changed to allow implementations to continue to implement the Ada 83 Small attribute. This was always intended to be allowed.

16.i/2
\{AI95-00235-01\} The note about resolving prefixes of attributes was updated to reflect that the prefix of an Access attribute now has an expected type (see 3.10.2).

Wording Changes from Ada 2005

16.j/3
\{AI05-0006-1\} Correction: Defined the nominal subtype of an attribute_reference to close a minor language hole.

4.1.5 User-Defined References

Static Semantics

1/3
\{AI05-0139-2\} Given a discriminated_type T, the following type-related operational aspect may be specified:

4.1.4 Attributes
Implicit_Dereference

This aspect is specified by a name that denotes an access discriminant declared for the type \( T \).

Aspect Description for Implicit_Dereference: Mechanism for user-defined implicit .

{AI05-0139-2} A (view of a) type with a specified Implicit_Dereference aspect is a reference type. A reference object is an object of a reference type. The discriminant named by the Implicit Dereference aspect is the reference discriminant of the reference type or reference object. [A generalized reference is a name that identifies a reference object, and denotes the object or subprogram designated by the reference discriminant of the reference object.]

Glossary entry: A reference type is one that has user-defined behavior for “.all”, defined by the Implicit_Dereference aspect.

Syntax

{AI05-0139-2} generalized_reference ::= reference_object_name

Name Resolution Rules

{AI05-0139-2} {AI05-0269-1} The expected type for the reference_object_name in a generalized_reference is any reference type.

Static Semantics

{AI05-0139-2} A generalized_reference denotes a view equivalent to that of a dereference of the reference discriminant of the reference object.

{AI05-0139-2} Given a reference type \( T \), the Implicit_Dereference aspect is inherited by descendants of type \( T \) if not overridden. If a descendant type constrains the value of the reference discriminant of \( T \) by a new discriminant, that new discriminant is the reference discriminant of the descendant. [If the descendant type constrains the value of the reference discriminant of \( T \) by an expression other than the name of a new discriminant, a generalized_reference that identifies an object of the descendant type denotes the object or subprogram designated by the value of this constraining expression.]

Dynamic Semantics

{AI05-0139-2} The evaluation of a generalized_reference consists of the evaluation of the reference_object_name and a determination of the object or subprogram designated by the reference discriminant of the named reference object. A check is made that the value of the reference discriminant is not the null access value. Constraint Error is raised if this check fails. The generalized_reference denotes the object or subprogram designated by the value of the reference discriminant of the named reference object.

Examples

{AI05-0268-1} type Barrel is tagged ... -- holds objects of type Element
{AI05-0139-2} {AI05-0299-2} type Ref_Element(Data : access Element) is limited

private
with Implicit_Dereference => Data;

--- This Ref_Element type is a "reference" type.
--- "Data" is its reference discriminant.

{AI05-0139-2} {AI05-0268-1} function Find (B : aliased in out Barrel; Key : String)

return Ref_Element;

--- Return a reference to an element of a barrel.

{AI05-0268-1} {AI05-0299-2} B : aliased Barrel;

{AI05-0139-2} ...
Extensions to Ada 2005

The aspect Implicit_Dereference and the generalized_reference are new.

### 4.1.6 User-Defined Indexing

#### Static Semantics

**Given a tagged type** $T$, the following type-related, operational aspects may be specified:

**Constant Indexing**

This aspect shall be specified by a name that denotes one or more functions declared immediately within the same declaration list in which $T$ is declared. All such functions shall have at least two parameters, the first of which is of type $T$ or $T'\text{Class}$, or is an access-to-constant parameter with designated type $T$ or $T'\text{Class}$.

**Aspect Description for Constant Indexing:** Defines function(s) to implement user-defined indexed components.

**Variable Indexing**

This aspect shall be specified by a name that denotes one or more functions declared immediately within the same declaration list in which $T$ is declared. All such functions shall have at least two parameters, the first of which is of type $T$ or $T'\text{Class}$, or is an access parameter with designated type $T$ or $T'\text{Class}$. All such functions shall have a return type that is a reference type (see 4.1.5), whose reference discriminant is of an access-to-variable type.

**Reason:** We require these functions to return a reference type so that the object returned from the function can act like a variable. We need no similar rule for Constant Indexing, since all functions return constant objects.

**Aspect Description for Variable Indexing:** Defines function(s) to implement user-defined indexed components.

These aspects are inherited by descendants of $T$ (including the class-wide type $T'\text{Class}$). [The aspects shall not be overridden, but the functions they denote may be.]

**Ramification:** Indexing can be provided for multiple index types by overloading routines with different parameter profiles. For instance, the map containers provide indexing on both cursors and keys by providing pairs of overloaded routines to the Constant Indexing and Variable Indexing aspects.

**An indexable container type** is (a view of) a tagged type with at least one of the aspects Constant Indexing or Variable Indexing specified. An indexable container object is an object of an indexable container type. [A generalized indexing is a name that denotes the result of calling a function named by a Constant Indexing or Variable Indexing aspect.]

**Glossary entry:** An indexable container type is one that has user-defined behavior for indexing, via the Constant Indexing or Variable Indexing aspects.

**Legality Rules**

**The Constant Indexing or Variable Indexing aspect shall not be specified:**

- on a derived type if the parent type has the corresponding aspect specified or inherited; or
- on a full_type_declaration if the type has a tagged partial view.

In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

**Ramification:** In order to enforce these rules without breaking privacy, we cannot allow a tagged private type to have hidden indexing aspects. There is no problem if the private type is not tagged (as the indexing aspects cannot be specified on descendants in that case).
We don't need an assume-the-worst rule as deriving from formal tagged type is not allowed in generic bodies.

Syntax

\begin{verbatim}
{AI05-0139-2} {AI05-0292-1} generalized_indexing ::= 
    indexable_container_object_prefix actual_parameter_part
\end{verbatim}

Name Resolution Rules

\begin{verbatim}
{AI05-0139-2} {AI05-0292-1} The expected type for the indexable_container_object_prefix of a 
generalized_indexing is any indexable container type.
\end{verbatim}

\begin{verbatim}
{AI05-0139-2} {AI05-0292-1} If the Constant_Indexing aspect is specified for the type of the 
indexable_container_object_prefix of a generalized_indexing, then the generalized_indexing is 
interpreted as a constant indexing under the following circumstances:
\begin{itemize}
    \item when the Variable_Indexing aspect is not specified for the type of the 
          indexable_container_object_prefix;
    \item when the indexable_container_object_prefix denotes a constant;
    \item when the generalized_indexing is used within a primary where a name denoting a constant is 
          permitted.
\end{itemize}

Ramification: This means it is not interpreted as a constant indexing for the variable name in the LHS of an 
assignment (not inside a primary), nor for the name used for an out or in out parameter (not allowed to be a constant), 
not for the name in an object renaming (not inside a primary), unless there is no Variable_Indexing aspect defined.

Otherwise, the generalized_indexing is interpreted as a variable indexing.

When a generalized_indexing is interpreted as a constant (or variable) indexing, it is equivalent to a call 
on a prefixed view of one of the functions named by the Constant_Indexing (or Variable_Indexing) aspect 
of the type of the indexable_container_object_prefix with the given actual_parameter_part, and with the 
indexable_container_object_prefix as the prefix of the prefixed view.

Ramification: In other words, the generalized_indexing is equivalent to:

\begin{verbatim}
indexable_container_object_prefix.Indexing actual_parameter_part
\end{verbatim}

where Indexing is the name specified for the Constant_Indexing or Variable_Indexing aspect.

Examples

\begin{verbatim}
{AI05-0268-1} {AI05-0292-1} type Indexed_Barrel is tagged ...
    with Variable_Indexing => Find;
    -- Indexed_Barrel is an indexable container type,
    -- Find is the generalized indexing operation.
{AI05-0268-1} function Find (B : aliased in out Indexed_Barrel; Key : String) return Ref_Element;
    -- Return a reference to an element of a barrel (see 4.1.5).
{AI05-0268-1} IB: aliased Indexed_Barrel;
{AI05-0268-1} -- All of the following calls are then equivalent:
    Find (IB,“pear”).Data.all := Element’(...); -- Traditional call
    IB.Find (“pear”).Data.all := Element’(...); -- Call of prefixed view
    IB.Find (“pear”) := Element’(...); -- Implicit dereference (see 4.1.5)
    IB (“pear”) := Element’(...); -- Implicit indexing and dereference
    IB (“pear”).Data.all := Element’(...); -- Implicit indexing only
\end{verbatim}

Extensions to Ada 2005

\begin{verbatim}
{AI05-0139-2} Aspects Constant_Indexing and Variable_Indexing, and the generalized_indexing syntax are new.
\end{verbatim}
4.2 Literals

[A literal represents a value literally, that is, by means of notation suited to its kind.] A literal is either a numeric_literal, a character_literal, the literal null, or a string_literal.

Discussion: An enumeration literal that is an identifier rather than a character_literal is not considered a literal in the above sense, because it involves no special notation “suited to its kind.” It might more properly be called an enumeration_identifier, except for historical reasons.

Name Resolution Rules

This paragraph was deleted. {AI95-00230-01} The expected type for a literal null shall be a single access type.

Discussion: This new wording ("expected type ... shall be a single ... type") replaces the old "shall be determinable" stuff. It reflects an attempt to simplify and unify the description of the rules for resolving aggregates, literals, type conversions, etc. See 8.6, "The Context of Overload Resolution" for the details.

For a name that consists of a character_literal, either its expected type shall be a single character type, in which case it is interpreted as a parameterless function_call that yields the corresponding value of the character type, or its expected profile shall correspond to a parameterless function with a character result type, in which case it is interpreted as the name of the corresponding parameterless function declared as part of the character type's definition (see 3.5.1). In either case, the character_literal denotes the enumeration_literal_specification.

Discussion: See 4.1.3 for the resolution rules for a selector_name that is a character_literal.

The expected type for a primary that is a string_literal shall be a single string type.

Legality Rules

A character_literal that is a name shall correspond to a defining_character_literal of the expected type, or of the result type of the expected profile.

For each character of a string_literal with a given expected string type, there shall be a corresponding defining_character_literal of the component type of the expected string type.

This paragraph was deleted. {AI95-00230-01} {AI95-00231-01} A literal null shall not be of an anonymous access type, since such types do not have a null value (see 3.10).

Reason: This is a legality rule rather than an overloading rule, to simplify implementations.

Static Semantics

{AI95-00230-01} An integer literal is of type universal_integer. A real literal is of type universal_real. The literal null is of type universal_access.

Dynamic Semantics

The evaluation of a numeric literal, or the literal null, yields the represented value.

The evaluation of a string_literal that is a primary yields an array value containing the value of each character of the sequence of characters of the string_literal, as defined in 2.6. The bounds of this array value are determined according to the rules for positional_array_aggregates (see 4.3.3), except that for a null string literal, the upper bound is the predecessor of the lower bound.

For the evaluation of a string_literal of type T, a check is made that the value of each character of the string_literal belongs to the component subtype of T. For the evaluation of a null string literal, a check is made that its lower bound is greater than the lower bound of the base range of the index type. The exception Constraint_Error is raised if either of these checks fails.
Ramification: The checks on the characters need not involve more than two checks altogether, since one need only check the characters of the string with the lowest and highest position numbers against the range of the component subtype.

NOTES
6 Enumeration literals that are identifiers rather than character_literals follow the normal rules for identifiers when used in a name (see 4.1 and 4.1.3). Character_literals used as selector_names follow the normal rules for expanded names (see 4.1.3).

Examples of literals:

```
3.14159_26536  -- a real literal
1_345           -- an integer literal
'A'             -- a character literal
"Some Text"     -- a string literal
```

Incompatibilities With Ada 83

Because character_literals are now treated like other literals, in that they are resolved using context rather than depending on direct visibility, additional qualification might be necessary when passing a character_literal to an overloaded subprogram.

Extensions to Ada 83

Character_literals are now treated analogously to null and string_literals, in that they are resolved using context, rather than their content; the declaration of the corresponding defining_character_literal need not be directly visible.

Wording Changes from Ada 83

Name Resolution rules for enumeration literals that are not character_literals are not included anymore, since they are neither syntactically nor semantically "literals" but are rather names of parameterless functions.

Extensions to Ada 95

AI95-00230-01 AI95-00231-01 Null now has type universal_access, which is similar to other literals. Null can be used with anonymous access types.

4.3 Aggregates

[ An aggregate combines component values into a composite value of an array type, record type, or record extension.]

Syntax

```
aggregate ::= record_aggregate | extension_aggregate | array_aggregate
```

Name Resolution Rules

AI95-00287-01 The expected type for an aggregate shall be a single nonlimited array type, record type, or record extension.

Discussion: See 8.6, “The Context of Overload Resolution” for the meaning of “shall be a single ... type.”

Ramification: AI95-0005-1 There are additional rules for each kind of aggregate. These aggregate rules are additive; a legal expression needs to satisfy all of the applicable rules. That means the rule given here must be satisfied even when it is syntactically possible to tell which specific kind of aggregate is being used.

Legality Rules

An aggregate shall not be of a class-wide type.

Ramification: When the expected type in some context is class-wide, an aggregate has to be explicitly qualified by the specific type of value to be created, so that the expected type for the aggregate itself is specific.

Discussion: We used to disallow aggregates of a type with unknown discriminants. However, that was unnecessarily restrictive in the case of an extension aggregate, and irrelevant to a record aggregate (since a type that is legal for a
record aggregate could not possibly have unknown discriminants) and to an array aggregate (the only specific types that can have unknown discriminants are private types, private extensions, and types derived from them).

**Dynamic Semantics**

For the evaluation of an aggregate, an anonymous object is created and values for the components or ancestor part are obtained (as described in the subsequent subclause for each kind of the aggregate) and assigned into the corresponding components or ancestor part of the anonymous object. Obtaining the values and the assignments occur in an arbitrary order. The value of the aggregate is the value of this object.

5. For the evaluation of an aggregate, an anonymous object is created and values for the components or ancestor part are obtained (as described in the subsequent subclause for each kind of the aggregate) and assigned into the corresponding components or ancestor part of the anonymous object. Obtaining the values and the assignments occur in an arbitrary order. The value of the aggregate is the value of this object.

5.a **Discussion**: The ancestor part is the set of components inherited from the ancestor type. The syntactic category ancestor_part is the expression or subtype_mark that specifies how the ancestor part of the anonymous object should be initialized.

5.b **Ramification**: The assignment operations do the necessary value adjustment, as described in 7.6. Note that the value as a whole is not adjusted — just the subcomponents (and ancestor part, if any). 7.6 also describes when this anonymous object is finalized.

5.c If the ancestor_part is a subtype_mark the Initialize procedure for the ancestor type is applied to the ancestor part after default-initializing it, unless the procedure is abstract, as described in 7.6. The Adjust procedure for the ancestor type is not called in this case, since there is no assignment to the ancestor part as a whole.

6 If an aggregate is of a tagged type, a check is made that its value belongs to the first subtype of the type. Constraint_Error is raised if this check fails.

6.a **Ramification**: This check ensures that no values of a tagged type are ever outside the first subtype, as required for inherited dispatching operations to work properly (see 3.4). This check will always succeed if the first subtype is unconstrained. This check is not extended to untagged types to preserve upward compatibility.

**Extensions to Ada 83**

6. We now allow extension_aggregates.

**Wording Changes from Ada 83**

6.c We have adopted new wording for expressing the rule that the type of an aggregate shall be determinable from the outside, though using the fact that it is nonlimited record (extension) or array.

6.d An aggregate now creates an anonymous object. This is necessary so that controlled types will work (see 7.6).

**Incompatibilities With Ada 95**

6.e/2 {AI95-00287-01} In Ada 95, a limited type is not considered when resolving an aggregate. Since Ada 2005 now allows limited aggregates, we can have incompatibilities. For example:

```
6.f/2 type Lim is limited
     record
           Comp: Integer;
     end record;

6.g/2 type Not_Lim is
     record
           Comp: Integer;
     end record;

6.h/2 procedure P(X: Lim);
procedure P(X: Not_Lim);
```

6.i/2 The call to P is ambiguous in Ada 2005, while it would not be ambiguous in Ada 95 as the aggregate could not have a limited type. Qualifying the aggregate will eliminate any ambiguity. This construction would be rather confusing to a maintenance programmer, so it should be avoided, and thus we expect it to be rare.

**Extensions to Ada 95**

6.k/2 {AI95-00287-01} Aggregates can be of a limited type.
4.3.1 Record Aggregates

[In a record_aggregate, a value is specified for each component of the record or record extension value, using either a named or a positional association.]

Syntax

record_aggregate ::= (record_component_association_list)
record_component_association_list ::= record_component_association { , record_component_association } | null record
{AI95-00287-01} record_component_association ::= [component_choice_list => ] expression
  | component_choice_list => <>
component_choice_list ::= component_selector_name { | component_selector_name }
  | others

A record_component_association is a named component association if it has a component_choice_list; otherwise, it is a positional component association. Any positional component associations shall precede any named component associations. If there is a named association with a component_choice_list of others, it shall come last.

Discussion: These rules were implied by the BNF in an early version of the RM9X, but it made the grammar harder to read, and was inconsistent with how we handle discriminant constraints. Note that for array aggregates we still express some of the rules in the grammar, but array aggregates are significantly different because an array aggregate is either all positional (with a possible others at the end), or all named.

In the record_component_association_list for a record_aggregate, if there is only one association, it shall be a named association.

Reason: {AI05-0264-1} Otherwise, the construct would be interpreted as a parenthesized expression. This is considered a syntax rule, since it is relevant to overload resolution. We choose not to express it with BNF so we can share the definition of record_component_association_list in both record_aggregate and extension_aggregate.

Ramification: The record_component_association_list of an extension_aggregate does not have such a restriction.

Name Resolution Rules

{AI95-00287-01} The expected type for a record_aggregate shall be a single nonlimited-record type or record extension.

Ramification: This rule is used to resolve whether an aggregate is an array_aggregate or a record_aggregate. The presence of a with is used to resolve between a record_aggregate and an extension_aggregate.

For the record_component_association_list of a record_aggregate, all components of the composite value defined by the aggregate are needed; for the association list of an extension_aggregate, only those components not determined by the ancestor expression or subtype are needed (see 4.3.2).] Each selector_name in a record_component_association_list shall denote a needed component [(including possibly a discriminant)].

Ramification: For the association list of a record_aggregate, “needed components” includes every component of the composite value, but does not include those in unchosen variants (see AI83-309). If there are variants, then the value specified for the discriminant that governs them determines which variant is chosen, and hence which components are needed.

If an extension defines a new known_discriminant_part, then all of its discriminants are needed in the component association list of an extension aggregate for that type, even if the discriminants have the same names and types as discriminants of the type of the ancestor expression. This is necessary to ensure that the positions in the record_component_association_list are well defined, and that discriminants that govern variant_parts can be given by static expressions.
The expected type for the expression of a record_component_association is the type of the associated component(s); the associated component(s) are as follows:

- For a positional association, the component [(including possibly a discriminant)] in the corresponding relative position (in the declarative region of the type), counting only the needed components;
- For a derived type (including type extensions), the order of declaration is defined in 3.4, “Derived Types and Classes”. In particular, all discriminants come first, regardless of whether they are defined for the parent type or are newly added to the derived type;
- For a named association with one or more component_selector_names, the named component(s);
- For a named association with the reserved word others, all needed components that are not associated with some previous association.

**Legality Rules**

If the type of a record_aggregate is a record extension, then it shall be a descendant of a record type, through one or more record extensions (and no private extensions).

The reserved words **null record** may appear only if there are no components needed in a given record_component_association_list; then the reserved words **null record** shall appear rather than a list of record_component_association.

For example, "(**null record**)" is a record_aggregate for a null record type. Similarly, "(**T'(A) with null record**)" is an extension_aggregate for a type defined as a null record extension of **T**.

If no components are needed and **null record** is not used, the record_component_association must necessarily be others => <>, as that is the only record_component_association that does not require an associated component.

Each record_component_association other than an others choice with a <> shall have at least one associated component, and each needed component shall be associated with exactly one record_component_association. If a record_component_association with an expression has two or more associated components, all of them shall be of the same type, or all of them shall be of anonymous access types whose subtypes statically match.

These rules apply to an association with an others choice with an expression. An others choice with a <> can match zero components or several components with different types.

Without these rules, there would be no way to know what was the expected type for the expression of the association. Note that some of the rules do not apply to <> associations, as we do not need to resolve anything. We allow others => <> to match no components as this is similar to array aggregates. That means that others => <> always represents a default-initialized record or array value.

Discussion: AI83-00244 also requires that the expression shall be legal for each associated component. This is because even though two components have the same type, they might have different subtypes. Therefore, the legality of the expression, particularly if it is an array aggregate, might differ depending on the associated component's subtype. However, we have relaxed the rules on array aggregates slightly for Ada 95, so the staticness of an applicable index constraint has no effect on the legality of the array aggregate to which it applies. See 4.3.3. This was the only case (that we know of) where a subtype provided by context affected the legality of an expression.

The rule that requires at least one associated component for each record_component_association implies that there can be no extra associations for components that don't exist in the composite value, or that are already determined by the ancestor expression or subtype of an extension_aggregate.

The second part of the first sentence ensures that no needed components are left out, nor specified twice.
Ramification: This expression might either be given within the aggregate itself, or in a constraint on the parent subtype in a derived_type_definition for some ancestor of the type of the aggregate.

\{A95-00287-01\} A record_component_association for a discriminant without a default expression shall have an expression rather than <>.

Reason: A discriminant must always have a defined value, but <> means uninitialized for a discrete type unless the component has a default value.

Dynamic Semantics

The evaluation of a recordAggregate consists of the evaluation of the record_component_association_list.

For the evaluation of a record_component_association_list, any per-object constraints (see 3.8) for components specified in the association list are elaborated and any expressions are evaluated and converted to the subtype of the associated component. Any constraint elaborations and expression evaluations (and conversions) occur in an arbitrary order, except that the expression for a discriminant is evaluated (and converted) prior to the elaboration of any per-object constraint that depends on it, which in turn occurs prior to the evaluation and conversion of the expression for the component with the per-object constraint.

Ramification: The conversion in the first rule might raise Constraint_Error.

Discussion: This check in the first rule presumably happened as part of the dependent compatibility check in Ada 83.

\{A95-00287-01\} For a record_component_association with an expression, the expression defines the value for the associated component(s). For a record_component_association with <>, if the component_declaration has a default_expression, that default_expression defines the value for the associated component(s); otherwise, the associated component(s) are initialized by default as for a stand-alone object of the component subtype (see 3.3.1).

The expression of a record_component_association is evaluated (and converted) once for each associated component.

Ramification: \{AI05-0005-1\} We don't need similar language for <>, as we're considering the value of <> for each individual component. Each component has its own default expression or its own default initialization (they can be different for each component, the components even could have different types), and each one has to be evaluated. So there is no need to repeat that.

NOTES

7 For a record aggregate with positional associations, expressions specifying discriminant values appear first since the known_discriminant_part is given first in the declaration of the type; they have to be in the same order as in the known_discriminant_part.

Examples

Example of a record aggregate with positional associations:

\{(4, July, 1776) -- see 3.8\}

Examples of record aggregates with named associations:

\{(Day => 4, Month => July, Year => 1776)\}
\{(Month => July, Day => 4, Year => 1776)\}
\{(Disk, Closed, Track => 5, Cylinder => 12) -- see 3.8.1\}
\{(Unit => Disk, Status => Closed, Cylinder => 9, Track => 1)\}

\{AI95-00287-01\} Example of component association with several choices:

\{(Value => 0, Succ|Pred => new Cell'(0, null, null)) -- see 3.10.1\}

-- The allocator is evaluated twice: Succ and Pred designate different cells

\{(Value => 0, Succ|Pred => <>\) -- see 3.10.1\}
Examples of record aggregates for tagged types (see 3.9 and 3.9.1):

- Expression'(null record)
- Literal'(Value => 0.0)
- Painted_Point'(0.0, Pi/2.0, Paint => Red)

Extensions to Ada 83

Null record aggregates may now be specified, via "(null record)". However, this syntax is more useful for null record extensions in extension aggregates.

Wording Changes from Ada 83

Various AIs have been incorporated (AI83-00189, AI83-00244, and AI83-00309). In particular, Ada 83 did not explicitly disallow extra values in a record aggregate. Now we do.

Extensions to Ada 95

{AI95-00287-01} <> can be used in place of an expression in a record_aggregate, default initializing the component.

Wording Changes from Ada 95

{AI95-00287-01} Limited record_aggregates are allowed (since all kinds of aggregates can now be limited, see 4.3).

Incompatibilities With Ada 2005

{AI05-0220-1} Correction: Corrected wording so that the rule for discriminants governing variant_parts was not effectively circular. The change makes a few aggregates where a nonstatic discriminant governs an empty variant_part illegal. However, most Ada implementations already enforce some version of the new rule and already reject these aggregates. So it is unlikely that any incompatibility will be noticed in practice.

{AI05-0221-1} Correction: Fixed the wording so that others => <> can be used in place of null record. This is needed to avoid a generic contract issue for generic bodies: we do not want to have to assume the worst to disallow others => <> if the record type might be a null record.

{AI05-0199-1} Correction: We now allow multiple components with anonymous access types to be specified with a single component association. This is to be consistent with the capabilities of a named access type.

4.3.2 Extension Aggregates

[An extension_aggregate specifies a value for a type that is a record extension by specifying a value or subtype for an ancestor of the type, followed by associations for any components not determined by the ancestor_part.]

Language Design Principles

The model underlying this syntax is that a record extension can also be viewed as a regular record type with an ancestor "prefix." The record_component_association_list corresponds to exactly what would be needed if there were no ancestor/prefix type. The ancestor_part determines the value of the ancestor/prefix.

Syntax

extension_aggregate ::= (ancestor_part with record_component_association_list)

ancestor_part ::= expression | subtype_mark

Name Resolution Rules

{AI95-00287-01} The expected type for an extension_aggregate shall be a single nonlimited-type that is a record extension. If the ancestor_part is an expression, it is expected to be of any nonlimited-tagged type.
Reason: We could have made the expected type \( T \)Class where \( T \) is the ultimate ancestor of the type of the aggregate, or we could have made it even more specific than that. However, if the overload resolution rules get too complicated, the implementation gets more difficult and it becomes harder to produce good error messages.

Ramification: \{AI05-0005-1\} This rule is additive with the rule given in 4.3. That means the 4.3 rule must be satisfied even though it is always syntactically possible to tell that something is an extension aggregate rather than another kind of aggregate. Specifically, that means that an extension aggregate is ambiguous if the context is overloaded on array and/or untagged record types, even though those are never legal contexts for an extension aggregate. Thus, this rule acts more like a Legality Rules than a Name Resolution Rules.

Legality Rules

\{AI95-00306-01\} \{AI05-0115-1\} If the ancestor_part is a subtype_mark, it shall denote a specific tagged subtype. If the ancestor_part is an expression, it shall not be dynamically tagged. The type of the extension_aggregate shall be a descendant of derived from the type of the ancestor_part (the ancestor type), through one or more record extensions (and no private extensions). If the ancestor_part is a subtype_mark, the view of the ancestor type from which the type is descended (see 7.3.1) shall not have unknown discriminants.

Reason: \{AI95-00306-01\} The expression cannot be dynamically tagged to prevent implicit "truncation" of a dynamically-tagged value to the specific ancestor type. This is similar to the rules in 3.9.2.

\{AI05-0067-1\} \{AI05-0244-1\} If the type of the ancestor_part is limited and at least one component is needed in the record_component_association_list, then the ancestor_part shall not be:

- a call to a function with an unconstrained result subtype; nor
- a parenthesized or qualified expression whose operand would violate this rule; nor
- a conditional_expression having at least one dependent_expression that would violate this rule.

Reason: \{AI05-0067-1\} \{AI05-0244-1\} This restriction simplifies implementation, because it ensures that either the caller or the callee knows the size to allocate for the aggregate. Without this restriction, information from both caller and callee would have to be combined to determine the appropriate size.

\{AI05-0067-1\} The (F(...) with null record) case is exempt from this rule, because such extension aggregates are created internally for inherited functions returning null-extension types — we can't very well make those illegal. Moreover, we don't need the rule for null extensions, as the result can simply use the space returned by the function call.

Static Semantics

For the record_component_association_list of an extension_aggregate, the only components needed are those of the composite value defined by the aggregate that are not inherited from the type of the ancestor_part, plus any inherited discriminants if the ancestor_part is a subtype_mark that denotes an unconstrained subtype.

Dynamic Semantics

For the evaluation of an extension_aggregate, the record_component_association_list is evaluated. If the ancestor_part is an expression, it is also evaluated; if the ancestor_part is a subtype_mark, the components of the value of the aggregate not given by the record_component_association_list are initialized by default as for an object of the ancestor type. Any implicit initializations or evaluations are performed in an arbitrary order, except that the expression for a discriminant is evaluated prior to any other evaluation or initialization that depends on it.

\{AI05-0282-1\} If the type of the ancestor_part has discriminants that are not inherited by the type of the extension_aggregate, then, unless the ancestor_part is not a subtype_mark that denotes an unconstrained subtype, a check is made that each discriminant determined by the ancestor_part of the ancestor has the value specified for a corresponding discriminant, if any, either in the record_component_association_list, or in the derived_type_definition for some ancestor of the type of the extension_aggregate. Constraint_Error is raised if this check fails.
4.3.2 Extension Aggregates

[In an \texttt{array\_aggregate}, a value is specified for each component of an array, either positionally or by its index.] For a positional \texttt{array\_aggregate}, the components are given in increasing-index order, with a

\section*{4.3.3 Array Aggregates}

\begin{itemize}
\item \textbf{Ramification:} Corresponding and specified discriminants are defined in 3.7. The rules requiring static compatibility between new discriminants of a derived type and the parent discriminant(s) they constrain ensure that at most one check is required per discriminant of the ancestor expression.
\item The check needs to be made any time that the ancestor is constrained; the source of the discriminants or the constraints is irrelevant.
\item Notes
\begin{enumerate}
\item If all components of the value of the \texttt{extension\_aggregate} are determined by the ancestor part, then the record-\texttt{component\_association\_list} is required to be simply \texttt{null record}.
\item If the ancestor part is a \texttt{subtype\_mark}, then its type can be abstract. If its type is controlled, then as the last step of evaluating the aggregate, the Initialize procedure of the ancestor type is called, unless the Initialize procedure is abstract (see 7.6).
\end{enumerate}
\item Examples of extension aggregates (for types defined in 3.9.1):
\begin{itemize}
\item \texttt{Painted\_Point'(Point with Red) (Point'\(P\) with Paint => Black)}
\item \texttt{(Expression with Left => 1.2, Right => 3.4)}
\item \texttt{Addition'(Binop with null record)} \hfill \texttt{-- presuming Binop is of type Binary\_Operation}
\end{itemize}
\item Extensions to Ada 83
\item The extension aggregate syntax is new.
\item Incompatibilities With Ada 95
\begin{itemize}
\item \textbf{Amendment Correction:} Eliminated implicit "truncation" of a dynamically tagged value when it is used as an ancestor expression. If an aggregate includes such an expression, it is illegal in Ada 2005. Such aggregates are thought to be rare; the problem can be fixed with a type conversion to the appropriate specific type if it occurs.
\end{itemize}
\item Wording Changes from Ada 95
\begin{itemize}
\item Limited \texttt{extension\_aggregates} are allowed (since all kinds of aggregates can now be limited, see 4.3).
\end{itemize}
\item Inconsistencies With Ada 2005
\begin{itemize}
\item \textbf{Correction:} An \texttt{extension\_aggregate} with an ancestor part whose discriminants are constrained and inherited might now raise \texttt{Constraint\_Error} if the aggregate's type is constrained, while it was OK in Ada 2005. In almost all cases, this will make no difference as the constraint will be checked by the immediately following use of the aggregate, but it is possible to compare such an aggregate for equality; in this case, no exception would be raised by Ada 2005, while Ada 2012 will raise \texttt{Constraint\_Error}. This should be very rare, and having the possibility means that the representation of the aggregate type has to be able to support unconstrained values of the type, even if the first subtype is constrained and no such objects can be created any other way.
\end{itemize}
\item Incompatibilities With Ada 2005
\begin{itemize}
\item \textbf{Correction:} A limited unconstrained ancestor expression that is a function call is now illegal unless the extension part is null. Such aggregates were first introduced in Ada 2005 and are very complex to implement as they must be built-in-place with an unknown size; as such, it is unlikely that they are implemented correctly in existing compilers and thus not often used in existing code.
\item \textbf{Correction:} An ancestor part that is a subtype with unknown discriminants is now explicitly illegal. Such a subtype should not be used to declare an object, and the ancestor part acts like an object. The Ada 95 rules did not disallow such cases, so it is possible that code exists that uses such an ancestor, but this should be rare.
\end{itemize}
An n-dimensional array_aggregate is one that is written as n levels of nested array_aggregates (or at the bottom level, equivalent string_literals). For the multidimensional case (n >= 2) the array_aggregates (or equivalent string_literals) at the n–1 lower levels are called subaggregates of the enclosing n-dimensional array_aggregate. The expressions of the bottom level subaggregates (or of the array_aggregate itself if one-dimensional) are called the array_component_expressions of the enclosing n-dimensional array_aggregate.

Ramification: Subaggregates do not have a type. They correspond to part of an array. For example, with a matrix, a subaggregate would correspond to a single row of the matrix. The definition of "n-dimensional" array_aggregate applies to subaggregates as well as aggregates that have a type.

To be honest: An others choice is the reserved word others as it appears in a positional_array_aggregate or as the discrete_choice of the discrete_choice_list in an array_component_association.

Name Resolution Rules

The expected type for an array_aggregate (that is not a subaggregate) shall be a single nonlimited array type. The component type of this array type is the expected type for each array_component_expression of the array_aggregate.

Ramification: {AI95-00287-01} We already require a single array or record type or record extension for an aggregate. The above rule requiring a single nonlimited array type (and similar ones for record and extension aggregates) resolves which kind of aggregate you have.

The expected type for each discrete_choice in any discrete_choice_list of a named_array_aggregate is the type of the corresponding index; the corresponding index for an array_aggregate that is not a subaggregate is the first index of its type; for an (n–m)-dimensional subaggregate within an array_aggregate of an n-dimensional type, the corresponding index is the index in position m+1.

Legality Rules

An array_aggregate of an n-dimensional array type shall be written as an n-dimensional array_aggregate.

Ramification: In an m-dimensional array_aggregate [including a subaggregate], where m >= 2, each of the expressions has to be an (m–1)-dimensional subaggregate.
An others choice is allowed for an array_aggregate only if an applicable index constraint applies to the array_aggregate. [An applicable index constraint is a constraint provided by certain contexts where an array_aggregate is permitted that can be used to determine the bounds of the array value specified by the aggregate.] Each of the following contexts (and none other) defines an applicable index constraint:

- {AI05-00318-02} For an explicit_actual_parameter, an explicit_generic_actual_parameter, the expression of a return_statement, the initialization expression in an object_declaration, or a default_expression [(for a parameter or a component)], when the nominal subtype of the corresponding formal parameter, generic formal parameter, function return_objectresult, object, or component is a constrained array subtype, the applicable index constraint is the constraint of the subtype;

- For the expression of an assignment_statement where the name denotes an array variable, the applicable index constraint is the constraint of the array variable;

  Reason: This case is broken out because the constraint comes from the actual subtype of the variable (which is always constrained) rather than its nominal subtype (which might be unconstrained).

- For the operand of a qualified_expression whose subtype_mark denotes a constrained array subtype, the applicable index constraint is the constraint of the subtype;

- For a component expression in an aggregate, if the component's nominal subtype is a constrained array subtype, the applicable index constraint is the constraint of the subtype;

  Discussion: Here, the array_aggregate with others is being used within a larger aggregate.

- {AI05-0147-1} For a parenthesized expression, the applicable index constraint is that, if any, defined for the expression:

  Discussion: RM83 omitted this case, presumably as an oversight. We want to minimize situations where an expression becomes illegal if parenthesized.

- {AI05-0147-1} For a conditional_expression, the applicable_index_constraint for each dependent_expression is that, if any, defined for the conditional_expression.

The applicable index constraint applies to an array_aggregate that appears in such a context, as well as to any subaggregates thereof. In the case of an explicit_actual_parameter (or default_expression) for a call on a generic formal subprogram, no applicable index constraint is defined.

  Reason: This avoids generic contract model problems, because only mode conformance is required when matching actual subprograms with generic formal subprograms.

- {AI05-0153-3} The discrete_choice_list of an array_component_association is allowed to have a discrete_choice that is a nonstatic choice_expression or that is a subtype_indication or ranged_choice_range that defines a nonstatic or null range, only if it is the single discrete_choice of its discrete_choice_list, and there is only one array_component_association in the array_aggregate.

  Discussion: We now allow a nonstatic others choice even if there are other array component expressions as well.

- {AI05-0262-1} In a named_array_aggregate where all discrete_choices are static, no two discrete_choices are allowed to cover the same value (see 3.8.1); if there is no others choice, the discrete_choices taken together shall exactly cover a contiguous sequence of values of the corresponding index type.

  Ramification: This implies that each component must be specified exactly once. See AI83-309.

  Reason: {AI05-0262-1} This has to apply even if there is only one static discrete_choice; a single choice has to represent a contiguous range (a subtype_mark with a static predicate might represent a discontiguous set of values). If the (single) choice is a dynamic subtype, we don't need to make this check as no predicates are allowed (see 3.2.4) and thus the range has to be contigious.

A bottom level subaggregate of a multidimensional array_aggregate of a given array type is allowed to be a string_literal only if the component type of the array type is a character type; each character of such a string_literal shall correspond to a defining_character_literal of the component type.

4.3.3 Array Aggregates
Static Semantics

A subaggregate that is a string_literal is equivalent to one that is a positional_array_aggregate of the same length, with each expression being the character_literal for the corresponding character of the string_literal.

Dynamic Semantics

The evaluation of an array_aggregate of a given array type proceeds in two steps:

1. Any discrete_choices of this aggregate and of its subaggregates are evaluated in an arbitrary order, and converted to the corresponding index type;

2. The array component expressions of the aggregate are evaluated in an arbitrary order and their values are converted to the component subtype of the array type; an array component expression is evaluated once for each associated component.

Ramification: Subaggregates are not separately evaluated. The conversion of the value of the component expressions to the component subtype might raise Constraint_Error.

\{AI05-0005-1\} We don't need to say that <> is evaluated once for each component, as <> means that each component is initialized by default. That means that the actions defined for default initialization are applied to each component individually. Initializing one component by default and copying that to the others would be an incorrect implementation in general (although it might be OK if the default initialization is known to be constant).

\{AI95-00287-01\} Each expression in an array_component_association defines the value for the associated component(s). For an array_component_association with <>, the associated component(s) are initialized by default as for a stand-alone object of the component subtype (see 3.3.1).

The bounds of the index range of an array_aggregate [(including a subaggregate)] are determined as follows:

- For an array_aggregate with an others choice, the bounds are those of the corresponding index range from the applicable index constraint;

- For a positional_array_aggregate [(or equivalent string_literal)] without an others choice, the lower bound is that of the corresponding index range in the applicable index constraint, if defined, or that of the corresponding index subtype, if not; in either case, the upper bound is determined from the lower bound and the number of expressions [(or the length of the string_literal)];

- For a named_array_aggregate without an others choice, the bounds are determined by the smallest and largest index values covered by any discrete_choice_list.

Reason: We don't need to say that each index value has to be covered exactly once, since that is a ramification of the general rule on aggregates that each component's value has to be specified exactly once.

For an array_aggregate, a check is made that the index range defined by its bounds is compatible with the corresponding index subtype.

Discussion: In RM83, this was phrased more explicitly, but once we define "compatibility" between a range and a subtype, it seems to make sense to take advantage of that definition.

Ramification: The definition of compatibility handles the special case of a null range, which is always compatible with a subtype. See AI83-00313.

\{AI05-0037-1\} For an array_aggregate with an others choice, a check is made that no expression or <> is specified for an index value outside the bounds determined by the applicable index constraint.

Discussion: RM83 omitted this case, apparently through an oversight. AI83-00309 defines this as a dynamic check, even though other Ada 83 rules ensured that this check could be performed statically. We now allow an others choice to be dynamic, even if it is not the only choice, so this check now needs to be dynamic, in some cases. Also, within a generic unit, this would be a nonstatic check in some cases.

For a multidimensional array_aggregate, a check is made that all subaggregates that correspond to the same index have the same bounds.
30.a  Ramification: No array bounds “sliding” is performed on subaggregates.
30.b  Reason: If sliding were performed, it would not be obvious which subaggregate would determine the bounds of the corresponding index.

The exception Constraint_Error is raised if any of the above checks fail.

NOTES

10  {AI05-0004-1} In an array_aggregate, positional notation may only be used with two or more expressions; a single expression in parentheses is interpreted as a parenthesized_expression. A named_array_aggregate, such as (1 => X), may be used to specify an array with a single component.

Examples of array aggregates with positional associations:

((7, 9, 5, 1, 3, 2, 4, 8, 6, 0)
Table'(5, 8, 4, 1, others => 0)  -- see 3.6

Examples of array aggregates with named associations:

(1 .. 5 => (1 .. 8 => 0.0))  -- two-dimensional
(1 .. N => new Cell)  -- N new cells, in particular for N = 0
Table'(2 | 4 | 10 => 1, others => 0)
Schedule'(Mon .. Fri => True, others => False)  -- see 3.6
Schedule'(Wed | Sun => False, others => True)
Vector'(1 => 2.5)  -- single-component vector

Examples of two-dimensional array aggregates:

-- Three aggregates for the same value of subtype Matrix(1..2,1..3) (see 3.6):
((1.1, 1.2, 1.3), (2.1, 2.2, 2.3))
(1 => (1.1, 1.2, 1.3), 2 => (2.1, 2.2, 2.3))
(1 => (1 => 1.1, 2 => 1.2, 3 => 1.3), 2 => (1 => 2.1, 2 => 2.2, 3 => 2.3))

Examples of aggregates as initial values:

A : Table := (7, 9, 5, 1, 3, 2, 4, 8, 6, 0);  -- A(1)=7, A(10)=0
B : Table := (2 | 4 | 10 => 1, others => 0);  -- B(1)=0, B(10)=1
C : constant Matrix := (1 .. 5 => (1 .. 8 => 0.0));  -- C'Last(1)=5, C'Last(2)=8
D : Bit_Vector(M .. N) := (M .. N => True);  -- see 3.6
E : Bit_Vector(M .. N) := (others => True);
F : String(1 .. 1) := (1 => 'F');  -- a one component aggregate: same as "F"

{AI95-00433-01} Example of an array aggregate with defaulted others choice and with an applicable index constraint provided by an enclosing record aggregate:

Buffer'(Size => 50, Pos => 1, Value => String'('x', others => <>))  -- see 3.7
The legality of an *others* choice is no longer affected by the staticness of the applicable index constraint. This substantially simplifies several rules, while being slightly more flexible for the user. It obviates the rulings of AI83-00244 and AI83-00310, while taking advantage of the dynamic nature of the "extra values" check required by AI83-00309.

Named array aggregates are permitted even if the index type is descended from a formal scalar type. See 4.9 and AI83-00190.

### Wording Changes from Ada 83

We now separate named and positional array aggregate syntax, since, unlike other aggregates, named and positional associations cannot be mixed in array aggregates (except that an *others* choice is allowed in a positional array aggregate).

We have also reorganized the presentation to handle multidimensional and one-dimensional aggregates more uniformly, and to incorporate the rulings of AI83-00019, AI83-00309, etc.

### Extensions to Ada 95

{AI95-00287-01} *<>* can be used in place of an *expression* in an *array_aggregate*, default-initializing the component.

### Wording Changes from Ada 95

{AI95-00287-01} Limited *array_aggregates* are allowed (since all kinds of aggregates can now be limited, see 4.3).

{AI95-00318-02} Fixed *aggregates* to use the subtype of the return object of a function, rather than the result subtype, because they can differ for an *extended_return_statement*, and we want to use the subtype that's explicitly in the code at the point of the *expression*.

### Inconsistencies With Ada 2005

{AI05-0037-1} **Correction**: Fixed so the check for components outside of the array applies to both *expressions* and *<*>s. As *<>* was a new feature in Ada 2005, there should be little existing code that depends on a *<>* component that is specified outside of the array (and that is nonsense anyway, that a compiler is likely to detect even without an explicit language rule disallowing it).

### Wording Changes from Ada 2005

{AI05-0147-1} Added a definition of the applicable index constraint for *conditional_expressions* (which are new).

### 4.4 Expressions

{AI05-0147-1} {AI05-0158-1} {AI05-0176-1} An *expression* is a formula that defines the computation or retrieval of a value. In this International Standard, the term "expression" refers to a construct of the syntactic category *expression* or of any of the following categories: *choice_expression*, *choice_relation*, *relation*, *simple_expression*, *term*, *factor*, *primary*, *conditional_expression*, *quantified_expression* and other five syntactic categories defined below.

#### Syntax

expression ::= relation {and relation} | relation {and then relation} | relation {or relation} | relation {or else relation} | relation {xor relation}

{AI05-0158-1} *choice_expression* ::= choice_relation {and choice_relation} | choice_relation {or choice_relation} | choice_relation {xor choice_relation} | choice_relation {and then choice_relation} | choice_relation {or else choice_relation}

{AI05-0158-1} *choice_relation* ::= simple_expression [relational_operator simple_expression]
4.4 Expressions

A name used as a primary shall resolve to denote an object or a value.

Discussion: This replaces RM83-4.4(3). We don't need to mention named numbers explicitly, because the name of a named number denotes a value. We don't need to mention attributes explicitly, because attributes now denote (rather than yield) values in general. Also, the new wording allows attributes that denote objects, which should always have been allowed (in case the implementation chose to have such a thing).

Reason: It might seem odd that this is an overload resolution rule, but it is relevant during overload resolution. For example, it helps ensure that a primary that consists of only the identifier of a parameterless function is interpreted as a function_call rather than directly as a direct_name.

Static Semantics

Each expression has a type; it specifies the computation or retrieval of a value of that type.

Dynamic Semantics

The value of a primary that is a name denoting an object is the value of the object.

Implementation Permissions

For the evaluation of a primary that is a name denoting an object of an unconstrained numeric subtype, if the value of the object is outside the base range of its type, the implementation may either raise Constraint_Error or return the value of the object.

Ramification: This means that if extra-range intermediates are used to hold the value of an object of an unconstrained numeric subtype, a Constraint_Error can be raised on a read of the object, rather than only on an assignment to it. Similarly, it means that computing the value of an object of such a subtype can be deferred until the first read of the object (presuming no side effects other than failing an Overflow_Check are possible). This permission is over and above that provided by subclause 11.6, since this allows the Constraint_Error to move to a different handler.

Reason: This permission is intended to allow extra-range registers to be used efficiently to hold parameters and local variables, even if they might need to be transferred into smaller registers for performing certain predefined operations.

Discussion: There is no need to mention other kinds of primaries, since any Constraint_Error to be raised can be “charged” to the evaluation of the particular kind of primary.
Examples of primaries:

4.0                -- real literal
Pi                 -- named number
(1 .. 10 => 0)     -- array aggregate
Sum                -- variable
Integer'Last       -- attribute
Sine(X)            -- function call
Color'(Blue)       -- qualified expression
Real(M*N)          -- conversion
(Line_Count + 10)  -- parenthesized expression

Examples of expressions:

{AI95-00433-01} Volume                      -- primary
not Destroyed               -- factor
2*Line_Count                -- term
-4.0                        -- simple expression
-4.0 + A                    -- simple expression
B**2 - 4.0*A*C              -- simple expression
R*Sin(θ)*Cos(φ)             -- simple expression
Password(1 .. 3) = "Bwv"    -- relation
Count in Small_Int          -- relation
Count not in Small_Int      -- relation
Index = 0 or Item_Hit       -- expression
(Cold and Sunny) or Warm    -- expression (parentheses are required)
A**(B**C)                   -- expression (parentheses are required)

Extensions to Ada 83

In Ada 83, out parameters and their nondiscriminant subcomponents are not allowed as primaries. These restrictions are eliminated in Ada 95.

In various contexts throughout the language where Ada 83 syntax rules had simple_expression, the corresponding Ada 95 syntax rule has expression instead. This reflects the inclusion of modular integer types, which makes the logical operators "and", "or", and "xor" more useful in expressions of an integer type. Requiring parentheses to use these operators in such contexts seemed unnecessary and potentially confusing. Note that the bounds of a range still have to be specified by simple_expressions, since otherwise expressions involving membership tests might be ambiguous. Essentially, the operation ".." is of higher precedence than the logical operators, and hence uses of logical operators still have to be parenthesized when used in a bound of a range.

Wording Changes from Ada 2005

{AI05-0003-1} Moved qualified_expression from primary to name (see 4.1). This allows the use of qualified_expressions in more places.

{AI05-0147-1} {AI05-0176-1} Added conditional_expression and quantified_expression to primary.

{AI05-0158-1} Expanded membership test syntax (see 4.5.2).

4.5 Operators and Expression Evaluation

[ The language defines the following six categories of operators (given in order of increasing precedence). The corresponding operator_symbols, and only those, can be used as designators in declarations of functions for user-defined operators. See 6.6, “Overloading of Operators”.]

Syntax

logical_operator ::= and | or | xor
relational_operator ::= = | /= | < | <= | > | >=
binary_adding_operator ::= + | – | &
unary_adding_operator ::= + | –
multiplying_operator ::= * | / | mod | rem
highest_precedence_operator ::=  ** | abs | not

Discussion: Some of the above syntactic categories are not used in other syntax rules. They are just used for classification. The others are used for both classification and parsing.

Static Semantics

For a sequence of operators of the same precedence level, the operators are associated with their operands in textual order from left to right. Parentheses can be used to impose specific associations.

Discussion: The left-associativity is not directly inherent in the grammar of 4.4, though in 1.1.4 the definition of the metasymbols {} implies left associativity. So this could be seen as redundant, depending on how literally one interprets the definition of the {} metasymbols.

See the Implementation Permissions below regarding flexibility in reassociating operators of the same precedence.

For each form of type definition, certain of the above operators are predefined; that is, they are implicitly declared immediately after the type definition. For each such implicit operator declaration, the parameters are called Left and Right for binary operators; the single parameter is called Right for unary operators.

[An expression of the form X op Y, where op is a binary operator, is equivalent to a function_call of the form "op"(X, Y). An expression of the form op Y, where op is a unary operator, is equivalent to a function_call of the form "op"(Y). The predefined operators and their effects are described in subclauses 4.5.1 through 4.5.6.]

Dynamic Semantics

[ The predefined operations on integer types either yield the mathematically correct result or raise the exception Constraint_Error. For implementations that support the Numerics Annex, the predefined operations on real types yield results whose accuracy is defined in Annex G, or raise the exception Constraint_Error. ]

To be honest: Predefined operations on real types can “silently” give wrong results when the Machine_Overflows attribute is false, and the computation overflows.

Implementation Requirements

The implementation of a predefined operator that delivers a result of an integer or fixed point type may raise Constraint_Error only if the result is outside the base range of the result type.

The implementation of a predefined operator that delivers a result of a floating point type may raise Constraint_Error only if the result is outside the safe range of the result type.

To be honest: An exception is made for exponentiation by a negative exponent in 4.5.6.

Implementation Permissions

For a sequence of predefined operators of the same precedence level (and in the absence of parentheses imposing a specific association), an implementation may impose any association of the operators with operands so long as the result produced is an allowed result for the left-to-right association, but ignoring the potential for failure of language-defined checks in either the left-to-right or chosen order of association.

Discussion: Note that the permission to reassociate the operands in any way subject to producing a result allowed for the left-to-right association is not much help for most floating point operators, since reassociation may introduce significantly different round-off errors, delivering a result that is outside the model interval for the left-to-right association. Similar problems arise for division with integer or fixed point operands.

Note that this permission does not apply to user-defined operators.

NOTES

11 The two operands of an expression of the form X op Y, where op is a binary operator, are evaluated in an arbitrary order, as for any function_call (see 6.4).
Examples

Examples of precedence:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>not Sunny or Warm</code></td>
<td>Same as <code>(not Sunny) or Warm</code></td>
</tr>
<tr>
<td><code>X &gt; 4.0 and Y &gt; 0.0</code></td>
<td>Same as <code>(X &gt; 4.0) and (Y &gt; 0.0)</code></td>
</tr>
<tr>
<td><code>-4.0*A**2</code></td>
<td>Same as <code>–(4.0 * (A**2))</code></td>
</tr>
<tr>
<td><code>abs(1 + A) + B</code></td>
<td>Same as <code>(abs (1 + A)) + B</code></td>
</tr>
<tr>
<td><code>Y**(-3)</code></td>
<td>Parentheses are necessary</td>
</tr>
<tr>
<td><code>A / B * C</code></td>
<td>Same as <code>(A/B)*C</code></td>
</tr>
<tr>
<td><code>A + (B + C)</code></td>
<td>Evaluate <code>B + C</code> before adding it to <code>A</code></td>
</tr>
</tbody>
</table>

Wording Changes from Ada 83

We don't give a detailed definition of precedence, since it is all implicit in the syntax rules anyway.

The permission to reassociate is moved here from RM83-11.6(5), so it is closer to the rules defining operator association.

4.5.1 Logical Operators and Short-circuit Control Forms

Name Resolution Rules

An expression consisting of two relations connected by and then or or else (a short-circuit control form) shall resolve to be of some boolean type; the expected type for both relations is that same boolean type.

Reason: This rule is written this way so that overload resolution treats the two operands symmetrically; the resolution of overloading present in either one can benefit from the resolution of the other. Furthermore, the type expected by context can help.

Static Semantics

The following logical operators are predefined for every boolean type `T`, for every modular type `T`, and for every one-dimensional array type `T` whose component type is a boolean type:

```ada
function "and"(Left, Right : T) return T
function "or"(Left, Right : T) return T
function "xor"(Left, Right : T) return T
```

This paragraph was deleted. To be honest: {AI95-00145-01} For predefined operators, the parameter and result subtypes shown as `T` are actually the unconstrained subtype of the type.

Ramification: {AI95-00145-01} For these operators, we are talking about the type without any (interesting) subtype, and not some subtype with a constraint or exclusion. Since it's possible that there is no name for the "uninteresting" subtype, we denote the type with an italicized `T`. This applies to the italicized `T` in many other predefined operators and attributes as well.

{AI95-00145-01} In many cases, there is a subtype with the correct properties available. The italicized `T` means:

- `T`Base, for scalars;
- the first subtype of `T`, for tagged types;
- a subtype of the type `T` without any constraint or null exclusion, in other cases.

Note that "without a constraint" is not the same as unconstrained. For instance, a record type with no discriminant part is considered constrained; no subtype of it has a constraint, but the subtype is still constrained.

Thus, the last case often is the same as the first subtype of `T`, but that isn’t the case for constrained array types (where the correct subtype is unconstrained) and for access types with a null exclusion (where the correct subtype does not exclude null).

This italicized `T` is used for defining operators and attributes of the language. The meaning is intended to be as described here.

For boolean types, the predefined logical operators and, or, and xor perform the conventional operations of conjunction, inclusive disjunction, and exclusive disjunction, respectively.

For modular types, the predefined logical operators are defined on a bit-by-bit basis, using the binary representation of the value of the operands to yield a binary representation for the result, where zero
represents False and one represents True. If this result is outside the base range of the type, a final subtraction by the modulus is performed to bring the result into the base range of the type.

The logical operators on arrays are performed on a component-by-component basis on matching components (as for equality — see 4.5.2), using the predefined logical operator for the component type. The bounds of the resulting array are those of the left operand.

**Dynamic Semantics**

The short-circuit control forms **and then** and **or else** deliver the same result as the corresponding predefined **and** and **or** operators for boolean types, except that the left operand is always evaluated first, and the right operand is not evaluated if the value of the left operand determines the result.

For the logical operators on arrays, a check is made that for each component of the left operand there is a matching component of the right operand, and vice versa. Also, a check is made that each component of the result belongs to the component subtype. The exception **Constraint_Error** is raised if either of the above checks fails.

Discussion: The check against the component subtype is per A183-00535.

NOTES

12 The conventional meaning of the logical operators is given by the following truth table:

<table>
<thead>
<tr>
<th>A</th>
<th>B</th>
<th>(A and B)</th>
<th>(A or B)</th>
<th>(A xor B)</th>
</tr>
</thead>
<tbody>
<tr>
<td>True</td>
<td>True</td>
<td>True</td>
<td>True</td>
<td>False</td>
</tr>
<tr>
<td>True</td>
<td>False</td>
<td>False</td>
<td>False</td>
<td>True</td>
</tr>
<tr>
<td>False</td>
<td>True</td>
<td>False</td>
<td>True</td>
<td>True</td>
</tr>
<tr>
<td>False</td>
<td>False</td>
<td>False</td>
<td>False</td>
<td>False</td>
</tr>
</tbody>
</table>

Examples of logical operators:

Sunny or Warm
Filter(1 .. 10) and Filter(15 .. 24) -- see 3.6.1

Examples of short-circuit control forms:

Next_Car.Owner /= null and then Next_Car.Owner.Age > 25 -- see 3.10.1
N = 0 or else A(N) = Hit_Value

### 4.5.2 Relational Operators and Membership Tests

[The **equality operators** = (equals) and /= (not equals) are predefined for nonlimited types. The other **relational operators** are the **ordering operators** < (less than), <= (less than or equal), > (greater than), and => (greater than or equal). The ordering operators are predefined for scalar types, and for **discrete array types**, that is, one-dimensional array types whose components are of a discrete type.

Ramification: The equality operators are not defined for every nonlimited type — see below for the exact rule.

A membership test, using **in** or **not in**, determines whether or not a value belongs to any given subtype or range, **is equal to any given value**, or has a tag that identifies a type that is covered by a given type. **or is convertible to and has an accessibility level appropriate for a given access type**. Membership tests are allowed for all types.]

**Name Resolution Rules**

The tested type of a membership test is the type of the range or the type determined by the **membership choices** of the **membership choice list**. Either all **membership choices** of the **membership choice list** shall resolve to the same type, which is the tested
type; or each membership_choice shall be of an elementary type, and the tested type shall be covered by each of these elementary types. If the tested type is tagged, then the simple_expression shall resolve to be of a type that is convertible (see 4.6) to covers or is covered by the tested type; if untagged, the expected type for the simple_expression is the tested type.

\{AI05-0158-1\} If the tested type is tagged, then the simple_expression shall resolve to be of a type that is convertible (see 4.6) to the tested type; if untagged, the expected type for the simple_expression is the tested type. The expected type of a choice_expression in a membership_choice, and of a simple_expression of a range in a membership_choice, is the tested type of the membership operation.

Reason: \{AI95-00230-01\} The part of the rule for untagged types is stated in a way that ensures that operands like a string literal null are still legal as operands of a membership test. \{AI95-00251-01\} The significance of “is convertible to covers or is covered by” is that we allow the simple_expression to be of any class-wide type that could be converted to covers the tested type, not just the one rooted at the tested type. This includes any class-wide type that covers the tested type, along with class-wide interfaces in some cases.

\{AI05-0158-1\} The special rule for determining the tested type for elementary types is to allow numeric literals in membership_choice lists. Without the rule, \texttt{A in B | 1} would be illegal as \texttt{B} and \texttt{1} would have different types (the literal having type \texttt{universal integer}).

Legality Rules

For a membership test, if the simple_expression is of a tagged class-wide type, then the tested type shall be (visibly) tagged.

Ramification: Untagged types covered by the tagged class-wide type are not permitted. Such types can exist if they are descendants of a private type whose full type is tagged. This rule is intended to avoid confusion since such derivatives don’t have their “own” tag, and hence are indistinguishable from one another at run time once converted to a covering class-wide type.

\{AI05-0158-1\} If a membership test includes one or more choice_expressions and the tested type of the membership test is limited, then the tested type of the membership test shall have a visible primitive equality operator.

Reason: \{AI05-0158-1\} A visible equality operator is required in order to avoid breaking privacy; that is, we don’t want to depend on a hidden equality operator.

Static Semantics

The result type of a membership test is the predefined type Boolean.

The equality operators are predefined for every specific type \(T\) that is not limited, and not an anonymous access type, with the following specifications:

\[
\begin{align*}
\text{function } \&= \text{ (Left, Right : } T \text{) return Boolean} \\
\text{function } \&/= \text{ (Left, Right : } T \text{) return Boolean}
\end{align*}
\]

\{AI95-00230-01\} The following additional equality operators for the universal_access type are declared in package Standard for use with anonymous access types:

\[
\begin{align*}
\text{function } \&= \text{ (Left, Right : universal_access) return Boolean} \\
\text{function } \&/= \text{ (Left, Right : universal_access) return Boolean}
\end{align*}
\]

The ordering operators are predefined for every specific scalar type \(T\), and for every discrete array type \(T\), with the following specifications:

\[
\begin{align*}
\text{function } < \text{ (Left, Right : } T \text{) return Boolean} \\
\text{function } <= \text{ (Left, Right : } T \text{) return Boolean} \\
\text{function } > \text{ (Left, Right : } T \text{) return Boolean} \\
\text{function } >= \text{ (Left, Right : } T \text{) return Boolean}
\end{align*}
\]
Name Resolution Rules

\{AI95-00230-01\} \{AI95-00420-01\} At least one of the operands of an equality operator for \texttt{universal access} shall be of a specific anonymous access type. Unless the predefined equality operator is identified using an expanded name with \texttt{prefix} denoting the package \texttt{Standard}, neither operand shall be of an access-to-object type whose designated type is \texttt{D} or \texttt{D}'\texttt{Class}, where \texttt{D} has a user-defined primitive equality operator such that:

- its result type is \texttt{Boolean};

\{AI05-0020-1\} it is declared immediately within the same declaration list as \texttt{D} or any partial or incomplete view of \texttt{D}; and

- at least one of its operands is an access parameter with designated type \texttt{D}.

\textbf{Reason:} The first sentence prevents compatibility problems by ensuring that these operators are not used for named access types. Also, universal access types do not count for the purposes of this rule. Otherwise, equality expressions like \texttt{(X = null)} would be ambiguous for normal access types.

\textbf{The rest of the rule makes it possible to call (including a dispatching call) user-defined "=\texttt{=}" operators for anonymous access-to-object types (they'd be hidden otherwise), and to write user-defined "=\texttt{=}" operations for anonymous access types (by making it possible to see the universal operator using the Standard prefix).}

\textbf{Ramification:} We don't need a similar rule for anonymous access-to-subprogram types because they can't be primitive for any type. Note that any nonprimitive user-defined equality operators still are hidden by the universal operators; they'll have to be called with a package prefix, but they are likely to be very uncommon.

Legality Rules

\{AI95-00230-01\} At least one of the operands of the equality operators for \texttt{universal access} shall be of type \texttt{universal access}, or both shall be of access-to-object types, or both shall be of access-to-subprogram types. Further:

- When both are of access-to-object types, the designated types shall be the same or one shall cover the other, and if the designated types are elementary or array types, then the designated subtypes shall statically match;

- When both are of access-to-subprogram types, the designated profiles shall be subtype conformant.

\textbf{Reason:} We don't want to allow completely arbitrary comparisons, as we don't want to insist that all access types are represented in ways that are convertible to one another. For instance, a compiler could use completely separate address spaces or incompatible representations. Instead, we allow compares if there exists an access parameter to which both operands could be converted. Since the user could write such an subprogram, and any reasonable meaning for "=\texttt{=}" would allow using it in such a subprogram, this doesn't impose any further restrictions on Ada implementations.

\{AI05-0123-1\} If the profile of an explicitly declared primitive equality operator of an untagged record type is type conformant with that of the corresponding predefined equality operator, the declaration shall occur before the type is frozen. In addition, if the untagged record type has a nonlimited partial view, then the declaration shall occur in the visible part of the enclosing package. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Dynamic Semantics

For discrete types, the predefined relational operators are defined in terms of corresponding mathematical operations on the position numbers of the values of the operands.

For real types, the predefined relational operators are defined in terms of the corresponding mathematical operations on the values of the operands, subject to the accuracy of the type.

\textbf{Ramification:} For floating point types, the results of comparing \textit{nearly} equal values depends on the accuracy of the implementation (see G.2.1, “Model of Floating Point Arithmetic” for implementations that support the Numerics Annex).
Implementation Note: On a machine with signed zeros, if the generated code generates both plus zero and minus zero, plus and minus zero must be equal by the predefined equality operators.

Two access-to-object values are equal if they designate the same object, or if both are equal to the null value of the access type.

Two access-to-subprogram values are equal if they are the result of the same evaluation of an Access attribute_reference, or if both are equal to the null value of the access type. Two access-to-subprogram values are unequal if they designate different subprograms. [It is unspecified whether two access values that designate the same subprogram but are the result of distinct evaluations of Access attribute_references are equal or unequal.]

Reason: This allows each Access attribute_reference for a subprogram to designate a distinct “wrapper” subprogram if necessary to support an indirect call.

{AI05-0123-1} For a type extension, predefined equality is defined in terms of the primitive [(possibly user-defined)] equals operator for of the parent type and for of any tagged components that have a record type_in the extension part, and predefined equality for any other components not inherited from the parent type.

Ramification: Two values of a type extension are not equal if there is a variant_part in the extension part and the two values have different variants present. This is a ramification of the requirement that a discriminant governing such a variant_part has to be a “new” discriminant, and so has to be equal in the two values for the values to be equal. Note that variant_parts in the parent part need not match if the primitive equals operator for the parent type considers them equal.

{AI95-00349-01} The full type extension's operation is used for a private extension. This follows as only full types have parent types, the type specified in a private extension is an ancestor, but not necessarily the parent type. For instance, in:

```ada
with Pak1;
package Pak2 is
   type Typ3 is new Pak1.Typ1 with private;
   private
      type Typ3 is new Pak1.Typ2 with null record;
   end Pak2;
```

the parent type is Pak1.Typ2, not Pak1.Typ1, and the equality operator of Pak1.Typ2 is used to create predefined equality for Typ3.

{AI05-0123-1} For a derived type whose parent is an untagged record type, predefined equality is defined in terms of the primitive (possibly user-defined) equals operator of the parent type.

Reason: This prevents predefined equality from reemerging in generic units for untagged record types. For other uses the primitive equality is inherited and the inherited routine is primitive.

{AI05-0123-1} For a private type, if its full type is a record type_tagged, predefined equality is defined in terms of the primitive equals operator of the full type; otherwise, if the full type is untagged, predefined equality for the private type is that of its full type.

For other composite types, the predefined equality operators [(and certain other predefined operations on composite types — see 4.5.1 and 4.6)] are defined in terms of the corresponding operation on matching components, defined as follows:

- For two composite objects or values of the same non-array type, matching components are those that correspond to the same component_declaration or discriminant_specification;
- For two one-dimensional arrays of the same type, matching components are those (if any) whose index values match in the following sense: the lower bounds of the index ranges are defined to match, and the successors of matching indices are defined to match;
- For two multidimensional arrays of the same type, matching components are those whose index values match in successive index positions.
The analogous definitions apply if the types of the two objects or values are convertible, rather than being the same.

Discussion: Ada 83 seems to omit this part of the definition, though it is used in array type conversions. See 4.6.

Given the above definition of matching components, the result of the predefined equals operator for composite types (other than for those composite types covered earlier) is defined as follows:

- If there are no components, the result is defined to be True;
- If there are unmatched components, the result is defined to be False;
- \{AI05-0123-1\} Otherwise, the result is defined in terms of the primitive equals operator for any matching tagged components that are records, and the predefined equals for any other matching untagged components.

Reason: \{AI05-0123-1\} This asymmetry between tagged and untagged components with and without a record type is necessary to preserve most upward compatibility and corresponds with the corresponding situation with generics, where the predefined operations “reemerge” in a generic for non-record tagged types, but do not for record tagged types. Also, only tagged types support user-defined assignment (see 7.6), so only tagged types can fully handle levels of indirection in the implementation of the type. For untagged types, one reason for a user-defined equals operator might be to allow values with different bounds or discriminants to compare equal in certain cases. When such values are matching components, the bounds or discriminants will necessarily match anyway if the discriminants of the enclosing values match.

Ramification: Two null arrays of the same type are always equal; two null records of the same type are always equal.

\{AI05-0123-1\} Note that if a composite object has a component of a floating point type, and the floating point type has both a plus and minus zero, which are considered equal by the predefined equality, then a block compare cannot be used for the predefined composite equality. Of course, with user-defined equals operators for tagged components that are records, a block compare breaks down anyway, so this is not the only special case that requires component-by-component comparisons. On a one’s complement machine, a similar situation might occur for integer types, since one’s complement machines typically have both a plus and minus (integer) zero.

To be honest: \{AI95-00230-01\} For a component with an anonymous access type, “predefined equality” is that defined for the universal access type (anonymous access types have no equality operators of their own).

\{AI05-0123-1\} For a component with a record tagged type \(T\), “the primitive equals operator” is the one with two parameters of \(T\) which returns Boolean. We’re not talking about some random other primitive function named “=”.

\{AI05-0123-1\} If the primitive equals operator for an untagged record type is abstract, then Program_Error is raised at the point of any (implicit) call to that abstract subprogram.

Reason: An explicit call to an abstract subprogram is illegal. This rule is needed in order to define the effect of an implicit call such as a call that is part of the predefined equality operation for an enclosing composite type that has a component of an untagged record type that has an abstract primitive equals operator. For tagged types, an abstract primitive equals operator is only allowed for an abstract type, and abstract types cannot be components, so this case does not occur.

\{8652/0016\} \{AI95-00123-01\} For any composite type, the order in which "=" is called for components is unspecified. Furthermore, if the result can be determined before calling "=" on some components, it is unspecified whether "=" is called on those components.

The predefined "/=" operator gives the complementary result to the predefined ":=" operator.

Ramification: Furthermore, if the user defines an ":=" operator that returns Boolean, then a ":=" operator is implicitly declared in terms of the user-defined ":=" operator so as to give the complementary result. See 6.6.

\{AI05-0264-1\} For a discrete array type, the predefined ordering operators correspond to lexicographic order using the predefined order relation of the component type: A null array is lexicographically less than any array having at least one component. In the case of nonnull arrays, the left operand is lexicographically less than the right operand if the first component of the left operand is less than that of the right; otherwise, the left operand is lexicographically less than the right operand only if their first components are equal and the tail of the left operand is lexicographically less than that of the right (the tail consists of the remaining components beyond the first and can be null).

4.5.2 Relational Operators and Membership Tests
An individual membership test is the membership test of a single membership choice. For the evaluation of a membership test using in whose membership choice list has a single membership choice, the simple expression and the membership choice range (if any) are evaluated in an arbitrary order; the result is the result of the individual membership test for the membership choice.

For the evaluation of a membership test using in whose membership choice list has more than one membership choice, the simple expression of the membership test is evaluated first and the result of the operation is equivalent to that of a sequence consisting of an individual membership test on each membership choice combined with the short-circuit control form or else.

**Ramification:** This equivalence includes the evaluation of the membership choices; evaluation stops as soon as an individual choice evaluates to True.

An individual membership test using in yields the result True if:

- The membership choice is a choice expression, and the simple expression is equal to the value of the membership choice. If the tested type is a record type or a limited type, the test uses the primitive equality for the type; otherwise, the test uses predefined equality.

- The membership choice is a range and the value of the simple expression belongs to the given range.

- The membership choice is a subtype mark, the tested type is scalar, and the value of the simple expression belongs to the given range, or the range of the named subtype, and the predicate of the named subtype evaluates to True; or

- The scalar membership test only does a range check and a predicate check. It does not perform any other check, such as whether a value falls in a “hole” of a “holey” enumeration type. The Pos attribute function can be used for that purpose.

Even though Standard.Float is an unconstrained subtype, the test “X in Float” will still return False (presuming the evaluation of X does not raise Constraint_Error) when X is outside Float'Range.

- The tested type is not scalar, and the value of the simple_expression satisfies any constraints of the named subtype, the predicate of the named subtype evaluates to True, and, if the type of the simple_expression is class-wide, the value has a tag that identifies a type covered by the tested type.

- If the type of the simple_expression is class-wide, the value has a tag that identifies a type covered by the tested type;

**Ramification:** Note that the tag is not checked if the simple_expression is of a specific type.

- If the tested type is an access type and the named subtype excludes null, the value of the simple_expression is not null.

- If the tested type is a general access-to-object type, the type of the simple_expression is convertible to the tested type and its accessibility level is no deeper than that of the tested type; further, if the designated type of the tested type is tagged and the simple_expression is nonnull, the tag of the object designated by the value of the simple_expression is covered by the designated type of the tested type.

Otherwise, the test yields the result False.

A membership test using not in gives the complementary result to the corresponding membership test using in.

**To be honest:** X not in A | B | C is intended to be exactly equivalent to not (X in A | B | C), including the order of evaluation of the simple_expression and membership choices.
Implementation Requirements

For all nonlimited types declared in language-defined packages, the "=" and "/=" operators of the type shall behave as if they were the predefined equality operators for the purposes of the equality of composite types and generic formal types.

Ramification: If any language-defined types are implemented with a user-defined "=" operator, then either the full type must be a record typetagged, or the compiler must use "magic" to implement equality for this type. A normal user-defined "=" operator for a non-record untaged type does not meet this requirement.

NOTES

This paragraph was deleted.

No exception is ever raised by a membership test, by a predefined ordering operator, or by a predefined equality operator for an elementary type, but an exception can be raised by the evaluation of the operands. A predefined equality operator for a composite type can only raise an exception if the type has a tagged part whose primitive equals operator propagates an exception.

If a composite type has components that depend on discriminants, two values of this type have matching components if and only if their discriminants are equal. Two nonnull arrays have matching components if and only if the length of each dimension is the same for both.

Examples

Examples of expressions involving relational operators and membership tests:

```
X /= Y
"a" < "Ab" and "A" < "Aa" -- True
"Aa" < "B" and "A" < "Aa" -- True
```

```
{AI05-0264-1} My_Car = null -- True if My_Car has been set to null (see 3.10.1)
My_Car = Your_Car -- True if we both share the same car
My_Car.all = Your_Car.all -- True if the two cars are identical
```

```
{AI05-0158-1} N not in 1..10 -- range membership test
Today in Mon..Fri -- range membership test
Card in Clubs | Spades -- list membership test (see 3.5.1)
Archive in Disk_Unit -- subtype membership test (see 3.8.1)
Tree.all in Addition'Class -- class membership test (see 3.9.1)
```

Extensions to Ada 83

```
39.a Membership tests can be used to test the tag of a class-wide value.
39.b Predefined equality for a composite type is defined in terms of the primitive equals operator for tagged components or the parent part.
```

Wording Changes from Ada 83

```
39.c The term “membership test” refers to the relation "X in S" rather to simply the reserved word in or not in.
39.d We use the term “equality operator” to refer to both the = (equals) and /= (not equals) operators. Ada 83 referred to = as the equality operator, and /= as the inequality operator. The new wording is more consistent with the ISO 10646 name for "=" (equals sign) and provides a category similar to “ordering operator” to refer to both = and /=.
39.e We have changed the term “catenate” to “concatenate”.
```

Extensions to Ada 95

```
49.1/2 The universal access equality operators are new. They provide equality operations (most importantly, testing against null) for anonymous access types.
```

Wording Changes from Ada 95
Inconsistencies With Ada 2005

\{AI05-0123-1\} User-defined untagged record equality is now defined to compose and be used in generics. Any code which assumes that the predefined equality reemerges in generics and in predefined equals for composite types could fail. However, it is much more likely that this change will fix bugs, as the behavior that would be expected (the user-defined "=" is used) will be true in more cases.

\{AI05-0123-1\} If a composite type contains a component of an untagged record type with an abstract equality operation, calling "=" on the composite type will raise Program_Error, while in the past a result will be returned using the predefined equality. This is quite possible in ASIS programs; it will detect a bug in such programs but of course the programs will need to be fixed before they will work.

Incompatibilities With Ada 2005

\{AI05-0123-1\} Late and hidden overriding of equality for untagged record types is now prohibited. This is necessary to make composition of equality predictable. It should always be possible to move the overriding to an earlier spot where it will be legal.

Extensions to Ada 2005

\{AI05-0149-1\} Membership tests for valid accessibility levels and tag coverage by the designated type for general access types are new.

\{AI05-0153-3\} Membership tests now include a predicate check.

\{AI05-0158-1\} Membership tests now allow multiple choices.

Wording Changes from Ada 2005

\{AI05-0020-1\} Correction: Wording was added to clarify that universal access "=" does not apply if an appropriate operator is declared for a partial or incomplete view of the designated type. Otherwise, adding a partial or incomplete view could make some "=" operators ambiguous.

4.5.3 Binary Adding Operators

Static Semantics

The binary adding operators + (addition) and – (subtraction) are predefined for every specific numeric type \(T\) with their conventional meaning. They have the following specifications:

\[
\text{function } + \text{(Left, Right : } T) \text{ return } T
\]

\[
\text{function } - \text{(Left, Right : } T) \text{ return } T
\]

The concatenation operators & are predefined for every nonlimited, one-dimensional array type \(T\) with component type \(C\). They have the following specifications:

\[
\text{function } & \text{(Left : } T; \text{ Right : } T) \text{ return } T
\]

\[
\text{function } & \text{(Left : } T; \text{ Right : } C) \text{ return } T
\]

\[
\text{function } & \text{(Left : } C; \text{ Right : } T) \text{ return } T
\]

\[
\text{function } & \text{(Left : } C; \text{ Right : } C) \text{ return } T
\]

Dynamic Semantics

For the evaluation of a concatenation with result type \(T\), if both operands are of type \(T\), the result of the concatenation is a one-dimensional array whose length is the sum of the lengths of its operands, and whose components comprise the components of the left operand followed by the components of the right operand. If the left operand is a null array, the result of the concatenation is the right operand. Otherwise, the lower bound of the result is determined as follows:

- If the ultimate ancestor of the array type was defined by a constrained_array_definition, then the lower bound of the result is that of the index subtype;
  
  \text{Reason: This rule avoids Constraint_Error when using concatenation on an array type whose first subtype is constrained.}

- If the ultimate ancestor of the array type was defined by an unconstrained_array_definition, then the lower bound of the result is that of the left operand.
[The upper bound is determined by the lower bound and the length.] A check is made that the upper bound of the result of the concatenation belongs to the range of the index subtype, unless the result is a null array. Constraint_Error is raised if this check fails.

If either operand is of the component type \( C \), the result of the concatenation is given by the above rules, using in place of such an operand an array having this operand as its only component (converted to the component subtype) and having the lower bound of the index subtype of the array type as its lower bound.

**Ramification:** The conversion might raise Constraint_Error. The conversion provides “sliding” for the component in the case of an array-of-arrays, consistent with the normal Ada 95 rules that allow sliding during parameter passing.

The result of a concatenation is defined in terms of an assignment to an anonymous object, as for any function call (see 6.5).

**Ramification:** This implies that value adjustment is performed as appropriate — see 7.6. We don't bother saying this for other predefined operators, even though they are all function calls, because this is the only one where it matters. It is the only one that can return a value having controlled parts.

**NOTES**

15. As for all predefined operators on modular types, the binary adding operators + and – on modular types include a final reduction modulo the modulus if the result is outside the base range of the type.

**Implementation Note:** A full "modulus" operation need not be performed after addition or subtraction of modular types. For binary moduli, a simple mask is sufficient. For nonbinary moduli, a check after addition to see if the value is greater than the high bound of the base range can be followed by a conditional subtraction of the modulus. Conversely, a check after subtraction to see if a "borrow" was performed can be followed by a conditional addition of the modulus.

**Examples of expressions involving binary adding operators:**

\[
Z + 0.1 \quad \text{-- } Z \text{ has to be of a real type}
\]

"A" & "BCD" \quad \text{-- } \text{concatenation of two string literals}

'\text{A}' & "BCD" \quad \text{-- } \text{concatenation of a character literal and a string literal}

'\text{A}' & '\text{A}' \quad \text{-- } \text{concatenation of two character literals}

**Inconsistencies With Ada 83**

The lower bound of the result of concatenation, for a type whose first subtype is constrained, is now that of the index subtype. This is inconsistent with Ada 83, but generally only for Ada 83 programs that raise Constraint_Error. For example, the concatenation operator in

```ada
X : array(1..10) of Integer;
beg
X := X(6..10) & X(1..5);
end
```

would raise Constraint_Error in Ada 83 (because the bounds of the result of the concatenation would be 6..15, which is outside of 1..10), but would succeed and swap the halves of X (as expected) in Ada 95.

**Extensions to Ada 83**

Concatenation is now useful for array types whose first subtype is constrained. When the result type of a concatenation is such an array type, Constraint_Error is avoided by effectively first sliding the left operand (if nonnull) so that its lower bound is that of the index subtype.

### 4.5.4 Unary Adding Operators

**Static Semantics**

The unary adding operators + (identity) and – (negation) are predefined for every specific numeric type \( T \) with their conventional meaning. They have the following specifications:

```ada
function "+"(Right : T) return T
function "-"(Right : T) return T
```
NOTES

16 For modular integer types, the unary adding operator –, when given a nonzero operand, returns the result of subtracting the value of the operand from the modulus; for a zero operand, the result is zero.

4.5.5 Multiplying Operators

Static Semantics

The multiplying operators * (multiplication), / (division), mod (modulus), and rem (remainder) are predefined for every specific integer type T:

function "*" (Left, Right : T) return T
function "/" (Left, Right : T) return T
function "mod" (Left, Right : T) return T
function "rem" (Left, Right : T) return T

Signed integer multiplication has its conventional meaning.

Signed integer division and remainder are defined by the relation:

\[ A = \left(\frac{A}{B}\right) \times B + (A \mod B) \]

where \((A \mod B)\) has the sign of \(A\) and an absolute value less than the absolute value of \(B\). Signed integer division satisfies the identity:

\[ \frac{-A}{B} = -\left(\frac{A}{B}\right) = \frac{A}{-B} \]

\{AI05-0260-1\} The signed integer modulus operator is defined such that the result of \(A \mod B\) is either zero, or has the sign of \(B\) and an absolute value less than the absolute value of \(B\); in addition, for some signed integer value \(N\), this result satisfies the relation:

\[ A = B \times N + (A \mod B) \]

The multiplying operators on modular types are defined in terms of the corresponding signed integer operators[, followed by a reduction modulo the modulus if the result is outside the base range of the type] [(which is only possible for the "*" operator)].

Ramification: The above identity satisfied by signed integer division is not satisfied by modular division because of the difference in effect of negation.

Multiplication and division operators are predefined for every specific floating point type T:

function "*"(Left, Right : T) return T
function "/"(Left, Right : T) return T

The following multiplication and division operators, with an operand of the predefined type Integer, are predefined for every specific fixed point type T:

function "*"(Left : T; Right : Integer) return T
function "/"(Left : T; Right : Integer) return T

[All of the above multiplying operators are usable with an operand of an appropriate universal numeric type.] The following additional multiplying operators for root_real are predefined[, and are usable when both operands are of an appropriate universal or root numeric type, and the result is allowed to be of type root_real, as in a number_declaration]:

Ramification: These operators are analogous to the multiplying operators involving fixed or floating point types where root_real substitutes for the fixed or floating point type, and root_integer substitutes for Integer. Only values of the corresponding universal numeric types are implicitly convertible to these root numeric types, so these operators are really restricted to use with operands of a universal type, or the specified root numeric types.

function "*"(Left, Right : root_real) return root_real
function "/"(Left, Right : root_real) return root_real
Multiplication and division between any two fixed point types are provided by the following two predefined operators:

**Ramification:** Universal_fixed is the universal type for the class of fixed point types, meaning that these operators take operands of any fixed point types (not necessarily the same) and return a result that is implicitly (or explicitly) convertible to any fixed point type.

- **Function:**
  - \( * \) (Left : root_real; Right : root_integer) return root_real
  - \( * \) (Left : root_integer; Right : root_real) return root_real
  - \( / \) (Left : root_real; Right : root_integer) return root_real

**Name Resolution Rules**

- {AI95-00364-01} {AI95-00420-01} The above two fixed-fixed multiplying operators shall not be used in a context where the expected type for the result is itself universal_fixed — the context has to identify some other numeric type to which the result is to be converted, either explicitly or implicitly. Unless the predefined universal operator is identified using an expanded name with prefix denoting the package Standard, an explicit conversion is required on the result when using the above fixed-fixed multiplication operator if either operand is of a type having a user-defined primitive multiplication operator such that:
  - {AI05-0020-1} {AI05-0209-1} it is declared immediately within the same declaration list as the type or any partial or incomplete view thereof; and
  - both of its formal parameters are of a fixed-point type.

- {AI95-00364-01} {AI95-00420-01} A corresponding requirement applies to the universal fixed-fixed division operator.

**Discussion:**

The small of universal_fixed is infinitesimal; no loss of precision is permitted. However, fixed-fixed division is impractical to implement when an exact result is required, and multiplication will sometimes result in unanticipated overflows in such circumstances, so we require an explicit conversion to be inserted in expressions like \( A * B * C \) if \( A, B, \) and \( C \) are each of some fixed point type.

On the other hand, \( X := A * B \); is permitted by this rule, even if \( X, A, \) and \( B \) are all of different fixed point types, since the expected type for the result of the multiplication is the type of \( X \), which is necessarily not universal_fixed.

**Legality Rules**

- {AI95-00364-01} The above two fixed-fixed multiplying operators shall not be used in a context where the expected type for the result is itself universal_fixed — [the context has to identify some other numeric type to which the result is to be converted, either explicitly or implicitly].

- Paragraph 20 was deleted.

**Dynamic Semantics**

The multiplication and division operators for real types have their conventional meaning. [For floating point types, the accuracy of the result is determined by the precision of the result type. For decimal fixed point types, the result is truncated toward zero if the mathematical result is between two multiples of the
small of the specific result type (possibly determined by context); for ordinary fixed point types, if the
mathematical result is between two multiples of the small, it is unspecified which of the two is the result.
]

The exception Constraint_Error is raised by integer division, rem, and mod if the right operand is zero.
[Similarly, for a real type T with T'Machine_Overflows True, division by zero raises Constraint_Error.]

NOTES
17 For positive A and B, A/B is the quotient and A rem B is the remainder when A is divided by B. The following relations are satisfied by the rem operator:

\[
\begin{align*}
A \mod (-B) &= A \mod B \\
(-A) \mod B &= -(A \mod B)
\end{align*}
\]

18 For any signed integer K, the following identity holds:

\[
A \mod B = (A + K \cdot B) \mod B
\]

The relations between signed integer division, remainder, and modulus are illustrated by the following table:

<table>
<thead>
<tr>
<th>A</th>
<th>B</th>
<th>A/B</th>
<th>A rem B</th>
<th>A mod B</th>
</tr>
</thead>
<tbody>

</tbody>
</table>

Incompatibilities With Ada 83

\{AI95-00364-01\} \{AI95-00420-01\} The universal fixed-fixed multiplying operators are now directly available (see below). Any attempt to use user-defined fixed-fixed multiplying operators will be ambiguous with the universal ones. The only way to use the user-defined operators is to fully qualify them in a prefix call. This problem was not documented during the design of Ada 95, and has been mitigated by Ada 2005.

35.a.1/2
Extensions to Ada 83

35.a
Explicit conversion of the result of multiplying or dividing two fixed point numbers is no longer required, provided the context uniquely determines some specific fixed point result type. This is to improve support for decimal fixed point, where requiring explicit conversion on every fixed-fixed multiply or divide was felt to be inappropriate.

35.b
The type universal_fixed is covered by universal_real, so real literals and fixed point operands may be multiplied or divided directly, without any explicit conversions required.

Wording Changes from Ada 83

35.c
We have used the normal syntax for function definition rather than a tabular format.

Incompatibilities With Ada 95

35.d2
{AI95-00364-01} We have changed the resolution rules for the universal fixed-fixed multiplying operators to remove the incompatibility with Ada 83 discussed above. The solution is to hide the universal operators in some circumstances. As a result, some legal Ada 95 programs will require the insertion of an explicit conversion around a fixed-fixed multiply operator. This change is likely to catch as many bugs as it causes, since it is unlikely that the user wanted to use predefined operators when they had defined user-defined versions.

Wording Changes from Ada 2005

35.e3
{AI05-0020-1} {AI05-0209-1} Correction: Wording was added to clarify that universal fixed "*" and "/" does not apply if an appropriate operator is declared for a partial (or incomplete) view of the designated type. Otherwise, adding a partial (or incomplete) view could make some "/" or "/" operators ambiguous.

35.f3
{AI05-0260-1} Correction: The wording for the mod operator was corrected so that a result of 0 does not have to have "the sign of B" (which is impossible if B is negative).

4.5.6 Highest Precedence Operators

Static Semantics

1 The highest precedence unary operator abs (absolute value) is predefined for every specific numeric type T, with the following specification:

   function "abs"(Right : T) return T

2 The highest precedence unary operator not (logical negation) is predefined for every boolean type T, every modular type T, and for every one-dimensional array type T whose components are of a boolean type, with the following specification:

   function "not"(Right : T) return T

3 The result of the operator not for a modular type is defined as the difference between the high bound of the base range of the type and the value of the operand. [For a binary modulus, this corresponds to a bitwise complement of the binary representation of the value of the operand.]

4 The operator not that applies to a one-dimensional array of boolean components yields a one-dimensional boolean array with the same bounds; each component of the result is obtained by logical negation of the corresponding component of the operand (that is, the component that has the same index value). A check is made that each component of the result belongs to the component subtype; the exception Constraint_Error is raised if this check fails.

   Discussion: The check against the component subtype is per AI83-00535.

5 The highest precedence exponentiation operator ** is predefined for every specific integer type T with the following specification:

   function "**"(Left : T; Right : Natural) return T

6 Exponentiation is also predefined for every specific floating point type as well as root_real, with the following specification (where T is root_real or the floating point type):

   function "**"(Left : T; Right : Integer'Base) return T
The right operand of an exponentiation is the exponent. The value of expression \( X^{N} \) with the value of the exponent \( N \) positive is the same as the value of equivalent to the expression \( X \times X \times \ldots \times X \) (with \( N-1 \) multiplications) except that the multiplications are associated in an arbitrary order. With \( N \) equal to zero, the result is one. With the value of \( N \) negative [(only defined for a floating point operand)], the result is the reciprocal of the result using the absolute value of \( N \) as the exponent.

**Ramification:** The language does not specify the order of association of the multiplications inherent in an exponentiation. For a floating point type, the accuracy of the result might depend on the particular association order chosen.

**Implementation Permissions**

The implementation of exponentiation for the case of a negative exponent is allowed to raise Constraint_Error if the intermediate result of the repeated multiplications is outside the safe range of the type, even though the final result (after taking the reciprocal) would not be. (The best machine approximation to the final result in this case would generally be 0.0.)

**NOTES**

19 As implied by the specification given above for exponentiation of an integer type, a check is made that the exponent is not negative. Constraint_Error is raised if this check fails.

**Inconsistencies With Ada 83**

{8652/0100} {AI95-00018-01} The definition of "**" allows arbitrary association of the multiplications which make up the result. Ada 83 required left-to-right associations (confirmed by AI83-00137). Thus it is possible that "**" would provide a slightly different (and more potentially accurate) answer in Ada 95 than in the same Ada 83 program.

**Wording Changes from Ada 83**

We now show the specification for "**" for integer types with a parameter subtype of Natural rather than Integer for the exponent. This reflects the fact that Constraint_Error is raised if a negative value is provided for the exponent.

**Wording Changes from Ada 2005**

{AI05-0088-1} **Correction:** The equivalence definition for "**" was corrected so that it does not imply that the operands are evaluated multiple times.

**4.5.7 Conditional Expressions**

{AI05-0147-1} {AI05-0188-1} {AI05-0262-1} A conditional_expression selects for evaluation at most one of the enclosed dependent_expressions, depending on a decision among the alternatives. One kind of conditional_expression is the if_expression, which selects for evaluation a dependent_expression depending on the value of one or more corresponding conditions. The other kind of conditional_expression is the case_expression, which selects for evaluation one of a number of alternative dependent_expressions; the chosen alternative is determined by the value of a selecting_expression.

**Language Design Principles**

{AI05-0188-1} As previously noted, there are two kinds of conditional_expression, if_expressions and case_expressions. Whenever possible, we have written the rules in terms of conditional_expressions to avoid duplication.

{AI05-0147-1} The rules for conditional_expressions have been designed as much as possible to work similarly to a parenthesized_expression. The intent is that as much as possible, wherever a parenthesized_expression would be allowed, a conditional_expression would be allowed, and it should work the same way.

**Syntax**

{AI05-0188-1} conditional_expression ::= if_expression | case_expression
if_expression ::= if condition then dependent_expression
     { elsif condition then dependent_expression }
     [ else dependent_expression ]

condition ::= boolean_expression

case_expression ::= case selecting_expression is
     case_expression_alternative { ,
     case_expression_alternative }

case_expression_alternative ::= when discrete_choice_list =>
     dependent_expression

Wherever the Syntax Rules allow an expression, a conditional_expression may be used in place of the expression, so long as it is immediately surrounded by parentheses.

Discussion: The syntactic category conditional_expression appears only as a primary that is parenthesized. The above rule allows it to additionally be used in other contexts where it would be directly surrounded by parentheses.

The grammar makes the following directly legal:

A := (if X then Y else Z); -- parentheses required
A := B + (if X then Y else Z) + C; -- parentheses required

The following procedure calls are syntactically legal; the first uses the above rule to eliminate the redundant parentheses found in the second:

P(if X then Y else Z);
P((if X then Y else Z)); -- redundant parentheses
P((if X then Y else Z), Some Other Param);
P(Some Other Param, (if X then Y else Z));
P(Formal => (if X then Y else Z));

whereas the following are illegal:

P(if X then Y else Z, Some Other Param);
P(Some Other Param, if X then Y else Z);
P(Formal => if X then Y else Z);

because in these latter cases, the conditional_expression is not immediately surrounded by parentheses (which means on both sides!).

The English-language rule applies in all places that could surround an expression with parentheses, including pragma arguments, type conversion and qualified expression operands, and array index expressions.

This English-language rule could have been implemented instead by adding a nonterminal expression_within_parentheses, which would consist of expressions and conditional_expressions. Then, that could be used in all of the syntax which could consist of parens directly around an expression. We did not do that because of the large amount of change required. A complete grammar is given in AI05-0147-1.

Implementation Note: Implementers are cautioned to consider error detection when implementing the syntax for conditional_expressions. An if expression and an if statement are very similar syntactically, (as are a case_expression and a case_statement) and simple mistakes can appear to change one into the other, potentially causing errors to be moved far away from their actual location. The absence of end if to terminate an if_expression (and end case for a case_expression) also may make error handling harder.

Name Resolution Rules

If a conditional_expression is expected to be of a type T, then each dependent_expression of the conditional_expression is expected to be of type T. Similarly, if a conditional_expression is expected to be of some class of types, then each dependent_expression of the conditional_expression is subject to the same expectation. If a conditional_expression shall resolve to be of a type T, then each dependent_expression shall resolve to be of type T.

The possible types of a conditional_expression are further determined as follows:
• If the conditional expression is the operand of a type conversion, the type of the conditional expression is the target type of the conversion; otherwise.

  **Reason:** This rule distributes an enclosing type conversion to the dependent expressions. This means that

  \[
  T(\text{if } C \text{ then } A \text{ else } B)
  \]

  has the same semantics as

  \[
  (\text{if } C \text{ then } T(A) \text{ else } T(B))
  \]

• If all of the dependent expressions are of the same type, the type of the conditional expression is that type; otherwise,

• If a dependent expression is of an elementary type, the type of the conditional expression shall be covered by that type; otherwise,

  **Reason:** This rule supports the use of numeric literals and universal expressions within a conditional expression.

• If the conditional expression is expected to be of type \( T \) or shall resolve to type \( T \), then the conditional expression is of type \( T \).

  **Ramification:** If the type of the conditional expression cannot be determined by one of these rules, then Name Resolution has failed for that expression, even if the dependent expressions would resolve individually.

  \{AI05-0147-1\} A condition is expected to be of any boolean type.

  \{AI05-0188-1\} The expected type for the selecting expression and the discrete choices are as for case statements (see 5.4).

**Legality Rules**

\{AI05-0147-1\} \{AI05-0188-1\} All of the dependent expressions shall be convertible (see 4.6) to the type of the conditional expression.

\{AI05-0147-1\} \{AI05-0188-1\} \{AI05-0269-1\} If the expected type of a conditional expression is a specific tagged type, all of the dependent expressions of the conditional expression shall be dynamically tagged, or none shall be dynamically tagged. In this case, the conditional expression is dynamically tagged if all of the dependent expressions are dynamically tagged, is tag-indeterminate if all of the dependent expressions are tag-indeterminate, and is statically tagged otherwise.

\{AI05-0147-1\} \{AI05-0262-1\} If there is no else dependent expression, the if expression shall be of a boolean type.

\{AI05-0188-1\} \{AI05-0269-1\} All Legality Rules that apply to the discrete choices of a case statement (see 5.4) also apply to the discrete choices of a case expression except within an instance of a generic unit.

  **Reason:** The exemption for a case expression that occurs in an instance allows the following example:

  ```ada
  generic
  with function Int Func return Integer;
package G is
     X : Float := (case Int Func is
                    when Integer'First .. -1 => -1.0,
                    when 0 => 0.0,
                    when Positive => 1.0);
end G;
function Nat Func return Natural is (123);
package I is new G (Int Func => Nat Func); -- Legal
```

  Note that the Legality Rules still apply in the generic unit itself; they are just not enforced in an instance of the unit.

**Dynamic Semantics**

\{AI05-0147-1\} \{AI05-0188-1\} For the evaluation of an if expression, the condition specified after if, and any conditions specified after elsif, are evaluated in succession (treating a final else as elsif True then), until one evaluates to True or all conditions are evaluated and yield False. If a condition evaluates
to True, the associated dependent expression is evaluated, converted to the type of the if expression, and the resulting value is the value of the if expression. Otherwise (when there is no else clause), the value of the if expression is True.

Ramification: Else is required unless the if expression has a boolean type, so the last sentence can only apply to if expressions with a boolean type.

\begin{itemize}
\item \[\text{AI05-0188-1}\] For the evaluation of a case expression, the selecting expression is first evaluated. If the value of the selecting expression is covered by the discrete choice list of some case expression alternative, then the dependent expression of the case expression alternative is evaluated, converted to the type of the case expression, and the resulting value is the value of the case expression. Otherwise (the value is not covered by any discrete choice list, perhaps due to being outside the base range), Constraint_Error is raised.
\end{itemize}

Extensions to Ada 2005

\begin{itemize}
\item \[\text{AI05-0147-1}\] If expressions and case expressions are new.
\end{itemize}

\section*{4.5.8 Quantified Expressions}

\subsection*{Syntax}

\begin{itemize}
\item \[\text{AI05-0176-1}\] quantified_expression ::= for quantifier loop_parameter_specification => predicate
\item \[\text{AI05-0176-1}\] quantified_expression ::= for quantifier iterator_specification => predicate
\item \[\text{AI05-0176-1}\] predicate ::= boolean_expression
\end{itemize}

Discussion: The syntactic category quantified_expression appears only as a primary that is parenthesized. The above rule allows it to additionally be used in other contexts where it would be directly surrounded by parentheses. This is the same rule that is used for conditional expressions; see 4.5.7 for a detailed discussion of the meaning and effects of this rule.

\subsection*{Name Resolution Rules}

\begin{itemize}
\item \[\text{AI05-0176-1}\] The expected type of a quantified_expression is any Boolean type. The predicate in a quantified_expression is expected to be of the same type.
\end{itemize}

\subsection*{Dynamic Semantics}

\begin{itemize}
\item \[\text{AI05-0176-1}\] For the evaluation of a quantified_expression, the loop parameter specification or iterator specification is first elaborated. The evaluation of a quantified_expression then evaluates the predicate for each value of the loop parameter. These values are examined in the order specified by the loop_parameter_specification (see 5.5) or iterator_specification (see 5.5.2).
\item \[\text{AI05-0176-1}\] The value of the quantified_expression is determined as follows:
\begin{itemize}
\item If the quantifier is all, the expression is True if the evaluation of the predicate yields True for each value of the loop parameter. It is False otherwise. Evaluation of the quantified_expression stops when all values of the domain have been examined, or when the predicate yields False for a given value. Any exception raised by evaluation of the predicate is propagated.
\item Ramification: The expression is True if the domain contains no values.
\item If the quantifier is some, the expression is True if the evaluation of the predicate yields True for some value of the loop parameter. It is False otherwise. Evaluation of the quantified_expression
\end{itemize}
\end{itemize}
stops when all values of the domain have been examined, or when the predicate yields True for a given value. Any exception raised by evaluation of the predicate is propagated.

Ramification: The expression is False if the domain contains no values.

Examples

\{AI05-0176-1\} The postcondition for a sorting routine on an array A with an index subtype T can be written:

\[
\text{Post} \implies (A'\text{Length} < 2 \text{ or else } \forall i \in A'\text{First} .. T'\text{Pred}(A'\text{Last}) \implies A(i) \leq A(T'\text{Succ}(i)))
\]

\{AI05-0176-1\} The assertion that a positive number is composite (as opposed to prime) can be written:

\[
\text{pragma Assert (for some } X \in 2 .. N / 2 \implies N \mod X = 0);\]

Extensions to Ada 2005

\{AI05-0176-1\} Quantified expressions are new.

4.6 Type Conversions

\{AI05-0299-1\} Explicit type conversions, both value conversions and view conversions, are allowed between closely related types as defined below. This subclause also defines rules for value and view conversions to a particular subtype of a type, both explicit ones and those implicit in other constructs.

Syntax

\[
type\_conversion ::= \\
\quad \text{subtype}\_mark(\text{expression}) \\
\quad | \text{subtype}\_mark(\text{name})
\]

The target subtype of a type_conversion is the subtype denoted by the subtype_mark. The operand of a type_conversion is the expression or name within the parentheses; its type is the operand type.

\{AI05-0299-1\} One type is convertible to a second type if a type_conversion with the first type as operand type and the second type as target type is legal according to the rules of this subclause.

Two types are convertible if each is convertible to the other.

Ramification: Note that “convertible” is defined in terms of legality of the conversion. Whether the conversion would raise an exception at run time is irrelevant to this definition.

\{8652/0017\} \{AI95-00184-01\} \{AI95-00330-01\} A type_conversion whose operand is the name of an object is called a view conversion if both its target type and operand type are tagged, or if it appears in a call as an actual parameter of mode \textbf{out} or \textbf{in out}; other type_conversions are called value conversions.

Ramification: A view conversion to a tagged type can appear in any context that requires an object name, including in an object renaming, the prefix of a selected_component, and if the operand is a variable, on the left side of an assignment_statement. View conversions to other types only occur as actual parameters. Allowing view conversions of untagged types in all contexts seemed to incur an undue implementation burden.

\{AI95-00330-01\} A type_conversion appearing as an in out parameter in a generic instantiation is not a view conversion; the second part of the rule only applies to subprogram calls, not instantiations.

Name Resolution Rules

The operand of a type_conversion is expected to be of any type.

Discussion: This replaces the "must be determinable" wording of Ada 83. This is equivalent to (but hopefully more intuitive than) saying that the operand of a type_conversion is a "complete context."
The operand of a view conversion is interpreted only as a name; the operand of a value conversion is interpreted as an expression.

**Reason:** This formally resolves the syntactic ambiguity between the two forms of type_conversion, not that it really matters.

---

### Legality Rules

#### {AI95-00251-01}

In a view conversion for an untagged type, the target type shall be convertible (back) to the operand type. If the target type is a numeric type, then the operand type shall be a numeric type.

**Reason:** Untagged view conversions appear only as [in] out parameters. Hence, the reverse conversion must be legal as well. The forward conversion must be legal even for an out parameter, because (for example) actual parameters of an access type are always copied in anyway.

---

#### {AI95-00251-01}

If the target type is an array type, then the operand type shall be an array type. Further:

- The types shall have the same dimensionality;
- Corresponding index types shall be convertible; and
- The component subtypes shall statically match;
- In a view conversion, the target type and the operand type shall both or neither have aliased components.

**Reason:** Without this rule, it is possible to violate the constrained status of aliased array components. Consider:

```ada
package P is
  type T is private;
  A : constant T := (D => 1);
  type A1 is array (1 .. 10) of aliased T;
  type A2 is array (1 .. 10) of T;
  type A (D : Integer := 0) is null record;
  A : constant T := (D => 1);
end P;
with P;
procedure Exam is
  X : P.A1;
  procedure S (Y : in out P.A2) is
  begin
    Y (1) := P.A;
  end;
  begin
    S (P.A (X)); -- This call will change the discriminant of X (t),
    -- so we cannot allow the conversion.
  end;
end Exam;
```

---

#### {AI95-00251-01}

If the target type is a general access type, then the operand type shall be an access-to-object type. Further:

**Discussion:** The Legality Rules and Dynamic Semantics are worded so that a type_conversion T(X) (where T is an access type) is (almost) equivalent to the attribute_reference X.allAccess, where the result is of type T. The type_conversion accepts a null value, whereas the attribute_reference would raise Constraint_Error.

---

#### {AI95-00251-01}

If the target type is an access-to-variable type, then the operand type shall be an access-to-variable type;
Ramification: If the target type is an access to constant type, then the operand type can be access to constant or access to variable.

- \{AI95-00251-01\} If the target designated type is tagged, then the operand designated type shall be convertible to the target designated type;

- \{AI95-00251-01\} If the target designated type is not tagged, then the designated types shall be the same, and either the designated subtypes shall statically match or the target designated subtype shall be discriminated and unconstrained; and.

Reason: These rules are designed to ensure that aliased array objects only need "dope" if their nominal subtype is unconstrained, but they can always have dope if required by the run-time model (since no sliding is permitted as part of access type conversion). By contrast, aliased discriminated objects will always need their discriminants stored with them, even if nominally constrained. (Here, we are assuming an implementation that represents an access value as a single pointer.)

- \{AI95-00251-01\} The accessibility level of the operand type shall not be statically deeper than that of the target type. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Ramification: The access parameter case is handled by a run-time check. Run-time checks are also done in instance bodied.

\{AI95-00251-01\} If the target type is an access to subprogram type, then the operand type shall be an access to subprogram type. Further:

- \{AI95-00251-01\} The designated profiles shall be subtype-conformant.

- \{AI95-00251-01\} The accessibility level of the operand type shall not be statically deeper than that of the target type. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. If the operand type is declared within a generic body, the target type shall be declared within the generic body.

Reason: The reason is illegal to convert from an access to subprogram type declared in a generic body to one declared outside that body is that in an implementation that shares generic bodies, procedures declared inside the generic need to have a different calling convention—they need an extra parameter pointing to the data declared in the current instance. For procedures declared in the spec, that's OK, because the compiler can know about them at compile time of the instantiation.

\{AI95-00251-01\} \{AI05-0115-1\} If there is a type (other than a root numeric type) that is an ancestor of both the target type and the operand type, or both types are class-wide types, then at least one of the following rules shall apply: If the target type is not included in any of the above four cases, there shall be a type that is an ancestor of both the target type and the operand type. Further, if the target type is tagged, then either:

- \{AI95-00251-01\} The target type shall be untagged; or

The operand type shall be covered by or descended from the target type; or

Ramification: This is a conversion toward the root, which is always safe.

- \{AI95-00251-01\} The operand type shall be a class-wide type that covers the target type; or.

Ramification: This is a conversion of a class-wide type toward the leaves, which requires a tag check. See Dynamic Semantics.

\{AI95-00251-01\} These two rules imply that a conversion from an ancestor parent type to a type extension is not permitted, as this would require specifying the values for additional components, in general, and changing the tag. An extension aggregate has to be used instead, constructing a new value, rather than converting an existing value. However, a conversion from the class-wide type rooted at an ancestor parent type is permitted; such a conversion just verifies that the operand's tag is a descendant of the target.

- \{AI95-00251-01\} The operand and target types shall both be class-wide types and the specific type associated with at least one of them shall be an interface type.

Ramification: We allow converting any class-wide type TClass to or from a class-wide interface type even if the specific type T does not have an appropriate interface ancestor, because some extension of T might have the needed
Ancestor. This is similar to a conversion of a class-wide type toward the leaves of the tree, and we need to be consistent. Of course, there is a run-time check that the actual object has the needed interface.

\section*{Types that are Inherently convertible}

\subsection*{24/3 \{AI95-00251-01\} \{AI05-0115-1\} If there is no type (other than a root numeric type) that is the ancestor of both the target type and the operand type, and they are not both class-wide types, one of the following rules shall apply: In a view conversion for an untagged type, the target type shall be convertible (back) to the operand type.

\paragraph*{Reason:} Untagged view conversions appear only as [in] out parameters. Hence, the reverse conversion must be legal as well. The forward conversion must be legal even if an out parameter, because actual parameters of an access type are always copied in anyway.

\begin{itemize}
  \item \{AI95-00251-01\} If the target type is a numeric type, then the operand type shall be a numeric type.
  \item \{AI95-00251-01\} If the target type is an array type, then the operand type shall be an array type. Further:
    \begin{itemize}
      \item \{AI95-00251-01\} The types shall have the same dimensionality;
      \item \{AI95-00251-01\} Corresponding index types shall be convertible;
      \item \{AI95-00251-01\} The component subtypes shall statically match;
    \end{itemize}
  \item \{AI95-00392-01\} If the component types are anonymous access types, then the accessibility level of the operand type shall not be statically deeper than that of the target type;
  \item \{AI95-00246-01\} Neither the target type nor the operand type shall be limited;
  \item \{AI95-00230-01\} \{AI95-00251-01\} If the target type is a general access-to-object type, then the operand type shall be universal access or an access-to-object type. Further, if the target type is a tagged, private, or volatile subcomponent, then the operand type shall have a tagged, private, or volatile subcomponent.
\end{itemize}

\paragraph*{Reason:} For unrelated array types, the component types could have different accessibility, and we had better not allow a conversion of a local type into a global type, in case the local type points at local objects. We don't need a check for other types of components; such components necessarily are for related types, and either have the same accessibility or (for access discriminants) cannot be changed so the discriminant check will prevent problems.

\paragraph*{Discussion:} Such a conversion cannot be written explicitly, of course, but it can be implicit (see below).

\begin{itemize}
  \item \{AI95-00230-01\} \{AI95-00251-01\} If the target type is an access-to-variable type, then the operand type shall be an access-to-variable type;
\end{itemize}

\paragraph*{Ramification:} These rules only apply to unrelated array conversions; different (weaker) rules apply to conversions between related types.

\paragraph*{Discussion:} The Legality Rules and Dynamic Semantics are worded so that a type conversion \texttt{T(X)} (where \texttt{T} is an access type) is (almost) equivalent to the attribute reference \texttt{X.allAccess}, where the result is of type \texttt{T}. The only difference is that the type conversion accepts a null value, whereas the attribute reference would raise \texttt{Constraint_Error}.

\paragraph*{Discussion:} If the target type is a general access-to-object type, then the operand type shall be \texttt{universal access} or an access-to-object type. Further, if the operand type is not \texttt{universal access}, then the operand type shall be an access-to-variable type;

\paragraph*{Ramification:} These rules only apply to unrelated array conversions; different (weaker) rules apply to conversions between related types.

\paragraph*{Discussion:} If the target type is an access-to-variable type, then the operand type shall be an access-to-variable type;
Ramification: If the target type is an access-to-constant type, then the operand type can be access-to-constant or access-to-variable.

- \{AI95-00251-01\} If the target designated type is tagged, then the operand designated type shall be convertible to the target designated type;

- \{AI95-00251-01\} \{AI95-00363-01\} If the target designated type is not tagged, then the designated types shall be the same, and either:
  - \{AI95-00363-01\} the designated subtypes shall statically match; or
  - \{AI95-00363-01\} \{AI95-00384-01\} the designated type shall be discriminated in its full view and unconstrained in any partial view, and one of the designated subtypes shall be unconstrained;

Ramification: \{AI95-00363-01\} This does not require that types have a partial view in order to allow the conversion, simply that any partial view that does exist is unconstrained.

\{AI95-00384-01\} This allows conversions both ways (either subtype can be unconstrained); while Ada 95 only allowed the conversion if the target subtype is unconstrained. We generally want type conversions to be symmetric; which type is the target shouldn't matter for legality.

Reason: These rules are designed to ensure that aliased array objects only need "dope" if their nominal subtype is unconstrained, but they can always have dope if required by the run-time model (since no sliding is permitted as part of access type conversion). By contrast, aliased discriminated objects will always need their discriminants stored with them, even if nominally constrained. (Here, we are assuming an implementation that represents an access value as a single pointer.)

- \{AI95-00251-01\} \{AI05-0148-1\} \{AI05-0248-1\} The accessibility level of the operand type shall not be statically deeper than that of the target type, unless the target type is an anonymous access type of a stand-alone object. If the target type is that of such a stand-alone object, the accessibility level of the operand type shall not be statically deeper than that of the declaration of the stand-alone object. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Ramification: \{AI05-0148-1\} The access parameter case is handled by a run-time check. Run-time checks are also done in instance bodies, and for stand-alone objects of anonymous access types.

Reason: We prohibit storing accesses to objects deeper than a stand-alone object of an anonymous access-to-object (even while we allow storing all other accesses) in order to prevent dangling accesses.

- \{AI95-00230-01\} If the target type is a pool-specific access-to-object type, then the operand type shall be universal access.

Reason: This allows null to be converted to pool-specific types. Without it, null could be converted to general access types but not pool-specific ones, which would be too inconsistent. Remember that these rules only apply to unrelated types, so we don't have to talk about conversions to derived or other related types.

- \{AI95-00230-01\} \{AI95-00251-01\} If the target type is an access-to-subprogram type, then the operand type shall be universal access or an access-to-subprogram type. Further, if the operand type is not universal access:
  - \{AI95-00251-01\} \{AI05-0239-1\} The designated profiles shall be subtype conformant subtype-conformant.
  - \{AI95-00251-01\} The accessibility level of the operand type shall not be statically deeper than that of the target type. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. If the operand type is declared within a generic body, the target type shall be declared within the generic body.

Reason: The reason it is illegal to convert from an access-to-subprogram type declared in a generic body to one declared outside that body is that in an implementation that shares generic bodies, procedures declared inside the generic need to have a different calling convention — they need an extra parameter pointing to the data declared in the
current instance. For procedures declared in the spec, that's OK, because the compiler can know about them at compile time of the instantiation.

Static Semantics

A type_conversion that is a value conversion denotes the value that is the result of converting the value of the operand to the target subtype.

\{AI05-0264-1\} A type_conversion that is a view conversion denotes a view of the object denoted by the operand. This view is a variable of the target type if the operand denotes a variable; otherwise, it is a constant of the target type.

The nominal subtype of a type_conversion is its target subtype.

Dynamic Semantics

For the evaluation of a type_conversion that is a value conversion, the operand is evaluated, and then the value of the operand is converted to a corresponding value of the target type, if any. If there is no value of the target type that corresponds to the operand value, Constraint_Error is raised; this can only happen on conversion to a modular type, and only when the operand value is outside the base range of the modular type. Additional rules follow:

- Numeric Type Conversion
  - If the target and the operand types are both integer types, then the result is the value of the target type that corresponds to the same mathematical integer as the operand.
  - If the target type is a decimal fixed point type, then the result is truncated (toward 0) if the value of the operand is not a multiple of the small of the target type.
  - If the target type is some other real type, then the result is within the accuracy of the target type (see G.2, “Numeric Performance Requirements”, for implementations that support the Numerics Annex).

Discussion: An integer type might have more bits of precision than a real type, so on conversion (of a large integer), some precision might be lost.

- If the target type is an integer type and the operand type is real, the result is rounded to the nearest integer (away from zero if exactly halfway between two integers).

Discussion: \{AI95-00267-01\} This was implementation defined in Ada 83. There seems no reason to preserve the nonportability in Ada 95. Round-away-from-zero is the conventional definition of rounding, and standard Fortran and COBOL both specify rounding away from zero, so for interoperability, it seems important to pick this. This is also the most easily “undone” by hand. Round-to-nearest-even is an alternative, but that is quite complicated if not supported by the hardware. In any case, this operation is not usually expected to be part of an inner loop, so predictability and portability are judged most important. We anticipate that a floating point attribute function Unbiased_Rounding will be provided (see A.5.3) for those applications that require round-to-nearest-even, and a floating point attribute function Machine_Rounding (also see A.5.3) is provided for those applications that require the highest possible performance. “Deterministic” rounding is required for static conversions to integer as well. See 4.9.

- Enumeration Type Conversion
  - The result is the value of the target type with the same position number as that of the operand value.

- Array Type Conversion
  - If the target subtype is a constrained array subtype, then a check is made that the length of each dimension of the value of the operand equals the length of the corresponding dimension of the target subtype. The bounds of the result are those of the target subtype.
  - If the target subtype is an unconstrained array subtype, then the bounds of the result are obtained by converting each bound of the value of the operand to the corresponding index.
type of the target type. For each nonnull index range, a check is made that the bounds of the range belong to the corresponding index subtype.

Discussion: Only nonnull index ranges are checked, per AI83-00313.

- In either array case, the value of each component of the result is that of the matching component of the operand value (see 4.5.2).

Ramification: This applies whether or not the component is initialized.

- {AI95-00392-01} If the component types of the array types are anonymous access types, then a check is made that the accessibility level of the operand type is not deeper than that of the target type.

Reason: This check is needed for operands that are access parameters and in instance bodies. Other cases are handled by the legality rule given previously.

• Composite (Non-Array) Type Conversion

- The value of each nondiscriminant component of the result is that of the matching component of the operand value.

Ramification: This applies whether or not the component is initialized.

- [The tag of the result is that of the operand.] If the operand type is class-wide, a check is made that the tag of the operand identifies a (specific) type that is covered by or descended from the target type.

Ramification: This check is certain to succeed if the operand type is itself covered by or descended from the target type.

Proof: The fact that a type_conversion preserves the tag is stated officially in 3.9, “Tagged Types and Type Extensions”

- For each discriminant of the target type that corresponds to a discriminant of the operand type, its value is that of the corresponding discriminant of the operand value; if it corresponds to more than one discriminant of the operand type, a check is made that all these discriminants are equal in the operand value.

- For each discriminant of the target type that corresponds to a discriminant that is specified by the derived_type_definition for some ancestor of the operand type (or if class-wide, some ancestor of the specific type identified by the tag of the operand), its value in the result is that specified by the derived_type_definition.

Ramification: It is a ramification of the rules for the discriminants of derived types that each discriminant of the result is covered either by this paragraph or the previous one. See 3.7.

- For each discriminant of the operand type that corresponds to a discriminant that is specified by the derived_type_definition for some ancestor of the target type, a check is made that in the operand value it equals the value specified for it.

- For each discriminant of the result, a check is made that its value belongs to its subtype.

• Access Type Conversion

- {AI05-0148-1} {AI05-0248-1} For an access-to-object type, a check is made that the accessibility level of the operand type is not deeper than that of the target type, unless the target type is an anonymous access type of a stand-alone object. If the target type is that of such a stand-alone object, a check is made that the accessibility level of the operand type is not deeper than that of the declaration of the stand-alone object; then if the check succeeds, the accessibility level of the target type becomes that of the operand type.

Ramification: {AI05-0148-1} This check is needed for operands that are access parameters, for stand-alone anonymous access objects, and in instance bodies.

Note that this check can never fail for the implicit conversion to the anonymous type of an access parameter that is done when calling a subprogram with an access parameter.
4.6 Type Conversions

• \{AI95-00230-01\} \{AI95-00231-01\} If the target type is an anonymous access type, a check is made that the value of the operand is not null; if the target is not an anonymous access type, then the result is null if the operand value is null, the result of the conversion is the null value of the target type.

**Ramification:** A conversion to an anonymous access type happens implicitly as part of initializing or assigning to an anonymous access object an access discriminant or access parameter.

**Reason:** \{AI95-00231-01\} As explained in 3.10, “Access Types”, it is important that a value of an anonymous access type can never be null.

• If the operand value is not null, then the result designates the same object (or subprogram) as is designated by the operand value, but viewed as being of the target designated subtype (or profile); any checks associated with evaluating a conversion to the target designated subtype are performed.

**Ramification:** The checks are certain to succeed if the target and operand designated subtypes statically match.

\{AI95-00231-01\} \{AI05-0153-3\} \{AI05-0290-1\} After conversion of the value to the target type, if the target subtype is constrained, a check is performed that the value satisfies this constraint. If the target subtype excludes null, then a check is made that the value is not null. If predicate checks are enabled for the target subtype (see 3.2.4), a check is performed that the predicate of the target subtype is satisfied for the value.

**Ramification:** \{AI95-00231-01\} The first above check above is a Range_Check for scalar subtypes, a Discriminant_Check or Index_Check for access subtypes, and a Discriminant_Check for discriminated subtypes. The Length_Check for an array conversion is performed as part of the conversion to the target type. The check for exclusion of null is an Access_Check.

For the evaluation of a view conversion, the operand name is evaluated, and a new view of the object denoted by the operand is created, whose type is the target type; if the target type is composite, checks are performed as above for a value conversion.

The properties of this new view are as follows:

• \{8652/0017\} \{AI95-00184-01\} If the target type is composite, the bounds or discriminants (if any) of the view are as defined above for a value conversion; each nondiscriminant component of the view denotes the matching component of the operand object; the subtype of the view is constrained if either the target subtype or the operand object is constrained, or if the target subtype is indefinite, or if the operand type is a descendant of the target type, and has discriminants that were not inherited from the target type;

• If the target type is tagged, then an assignment to the view assigns to the corresponding part of the object denoted by the operand; otherwise, an assignment to the view assigns to the object, after converting the assigned value to the subtype of the object (which might raise Constraint_Error);

• Reading the value of the view yields the result of converting the value of the operand object to the target subtype (which might raise Constraint_Error), except if the object is of an access type and the view conversion is passed as an out parameter; in this latter case, the value of the operand object is used to initialize the formal parameter without checking against any constraint of the target subtype (see 6.4.1).

**Reason:** This ensures that even an out parameter of an access type is initialized reasonably.

\{AI05-0290-1\} If an Accessibility_Check fails, Program_Error is raised. If a predicate check fails, Assertions.Assertion_Error is raised. Any other check associated with a conversion raises Constraint_Error if it fails.

Conversion to a type is the same as conversion to an unconstrained subtype of the type.
Reason: This definition is needed because the semantics of various constructs involves converting to a type, whereas an explicit type_conversion actually converts to a subtype. For example, the evaluation of a range is defined to convert the values of the expressions to the type of the range.

Ramiﬁcation: A conversion to a scalar type, or, equivalently, to an unconstrained scalar subtype, can raise Constraint_Error if the value is outside the base range of the type.

NOTES

20 In addition to explicit type_conversions, type conversions are performed implicitly in situations where the expected type and the actual type of a construct differ, as is permitted by the type resolution rules (see 8.6). For example, an integer literal is of the type universal_integer, and is implicitly converted when assigned to a target of some speciﬁc integer type. Similarly, an actual parameter of a speciﬁc tagged type is implicitly converted when the corresponding formal parameter is of a class-wide type.

Even when the expected and actual types are the same, implicit subtype conversions are performed to adjust the array bounds (if any) of an operand to match the desired target subtype, or to raise Constraint_Error if the (possibly adjusted) value does not satisfy the constraints of the target subtype.

21 {AI95-00330-01} A ramiﬁcation of the overload resolution rules is that the operand of an (explicit) type_conversion cannot be the_literal_null, an allocator, an aggregate, a string_literal, a character_literal, or an attribute_reference for an Access or Unchecked_Access attribute. Similarly, such an expression enclosed by parentheses is not allowed. A qualiﬁed_expression (see 4.7) can be used instead of such a type_conversion.

22 The constraint of the target subtype has no effect for a type_conversion of an elementary type passed as an out parameter. Hence, it is recommended that the ﬁrst subtype be speciﬁed as the target to minimize confusion (a similar recommendation applies to renaming and generic formal in out objects).

Examples of numeric type conversion:

Real(2*J) -- value is converted to ﬂoating point
Integer(1.6) -- value is 2
Integer(-0.4) -- value is 0

Example of conversion between derived types:

type A_Form is new B_Form;
X : A_Form;
Y : B_Form;
X := A_Form(Y);
Y := B_Form(X); -- the reverse conversion

Examples of conversions between array types:

type Sequence is array (Integer range <>) of Integer;
subtype Dozen is Sequence(1 .. 12);
Ledger : array (1 .. 100) of Integer;
Sequence(Ledger) -- bounds are those of Ledger
Sequence(Ledger(31 .. 42)) -- bounds are 31 and 42
Dozen(Ledger(31 .. 42)) -- bounds are those of Dozen

Incompatibilities With Ada 83

A character_literal is not allowed as the operand of a type_conversion, since there are now two character types in package Standard.

The component subtypes have to statically match in an array conversion, rather than being checked for matching constraints at run time.

Because sliding of array bounds is now provided for operations where it was not in Ada 83, programs that used to raise Constraint_Error might now continue executing and produce a reasonable result. This is likely to ﬁx more bugs than it creates.

Extensions to Ada 83

A type_conversion is considered the name of an object in certain circumstances (such a type_conversion is called a view conversion). In particular, as in Ada 83, a type_conversion can appear as an in out or out actual parameter. In
addition, if the target type is tagged and the operand is the name of an object, then so is the type_conversion, and it can be used as the prefix to a selected_component, in an object_renaming_declaration, etc.

We no longer require type-mark conformance between a parameter of the form of a type conversion, and the corresponding formal parameter. This had caused some problems for inherited subprograms (since there isn't really a type-mark for converted formals), as well as for renamings, formal subprograms, etc. See AI83-00245, AI83-00318, AI83-00547.

We now specify “deterministic” rounding from real to integer types when the value of the operand is exactly between two integers (rounding is away from zero in this case).

“Sliding” of array bounds (which is part of conversion to an array subtype) is performed in more cases in Ada 95 than in Ada 83. Sliding is not performed on the operand of a membership test, nor on the operand of a qualified_expression. It wouldn't make sense on a membership test, and we wish to retain a connection between subtype membership and subtype qualification. In general, a subtype membership test returns True if and only if a corresponding subtype qualification succeeds without raising an exception. Other operations that take arrays perform sliding.

Wording Changes from Ada 83

We no longer explicitly list the kinds of things that are not allowed as the operand of a type_conversion, except in a NOTE.

{AI05-0299-1} The rules in this subclause subsume the rules for "parameters of the form of a type conversion," and have been generalized to cover the use of a type conversion as a name.

Incompatibilities With Ada 95

Conversion rules for universal access were defined. These allow the use of anonymous access values in equality tests (see 4.5.2), and also allow the use of null in type conversions and other contexts that do not provide a single expected type.

A type conversion from an access-to-discriminated and unconstrained object to an access-to-discriminated and constrained one is allowed. Ada 95 only allowed the reverse conversion, which was weird and asymmetric. Of course, a constraint check will be performed for this conversion.

Wording Changes from Ada 95

Wording was added to ensure that view conversions are constrained, and that a tagged view conversion has a tagged object. Both rules are needed to avoid having a way to change the discriminants of a constrained object.

Wording was added to ensure that the aliased status of array components cannot change in a view conversion. This rule was needed to avoid having a way to change the discriminants of an aliased object. This rule was repealed later, as Ada 2005 allows changing the discriminants of an aliased object.

Wording was added to check subtypes that exclude null (see 3.10).

The organization of the legality rules was changed, both to make it clearer, and to eliminate an unintentional incompatibility with Ada 83. The old organization prevented type conversions between some types that were related by derivation (which Ada 83 always allowed).

Clarified that an untagged type conversion appearing as a generic actual parameter for a generic in out formal parameter is not a view conversion (and this is illegal). This confirms the ACATS tests, so all implementations already follow this interpretation.

4.6 Type Conversions 13 December 2012 236

4.6 Rules added by the Corrigendum to eliminate problems with discriminants of aliased components changing were removed, as we now generally allow discriminants of aliased components to be changed.

4.6.1 Accessibility checks on conversions involving types with anonymous access components were added. These components have the level of the type, and conversions can be between types at different levels, which could cause dangling access values in the absence of such checks.

Inconsistencies With Ada 2005

4.6.1 A stand-alone object of an anonymous access-to-object type now has dynamic accessibility. Normally, this will make programs legal that were illegal in Ada 2005. However, it is possible that a program that previously raised Program_Error now will not. It is very unlikely that an existing program intentionally depends on the exception being raised; the change is more likely to fix bugs than introduce them.

4.6.2 Wording Changes from Ada 2005

4.6.2.1 Correction: Clarified that a root numeric type is not considered a common ancestor for a conversion.

4.6.2.3 Added rules so that predicate aspects (see 3.2.4) are enforced on subtype conversion.

4.7 Qualified Expressions

[A qualified_expression is used to state explicitly the type, and to verify the subtype, of an operand that is either an expression or an aggregate.

Syntax

qualified_expression ::= subtype_mark'(expression) | subtype_mark'aggregate

Name Resolution Rules

The operand (the expression or aggregate) shall resolve to be of the type determined by the subtype mark, or a universal type that covers it.

Static Semantics

4.7.1 [If the operand of a qualified_expression denotes an object, the qualified_expression denotes a constant view of that object.] The nominal subtype of a qualified_expression is the subtype denoted by the subtype_mark.

Proof: {AI05-0003-1} This is stated in 3.3.

Dynamic Semantics

The evaluation of a qualified_expression evaluates the operand (and if of a universal type, converts it to the type determined by the subtype_mark) and checks that its value belongs to the subtype denoted by the subtype_mark. The exception Constraint_Error is raised if this check fails.

Ramification: This is one of the few contexts in Ada 95 where implicit subtype conversion is not performed prior to a constraint check, and hence no “sliding” of array bounds is provided.

Reason: Implicit subtype conversion is not provided because a qualified_expression with a constrained target subtype is essentially an assertion about the subtype of the operand, rather than a request for conversion. An explicit type_conversion can be used rather than a qualified_expression if subtype conversion is desired.

NOTES

23 When a given context does not uniquely identify an expected type, a qualified_expression can be used to do so. In particular, if an overloaded name or aggregate is passed to an overloaded subprogram, it might be necessary to qualify the operand to resolve its type.
Examples

Examples of disambiguating expressions using qualification:

```ada
type Mask is (Fix, Dec, Exp, Signif);
type Code is (Fix, Cla, Dec, Thz, Sub);

Print (Mask'((Dec))); -- Dec is of type Mask
Print (Code'((Dec))); -- Dec is of type Code

for J in Code'((Fix)) .. Code'((Dec)) loop ...
  -- qualification needed for either Fix or Dec
for J in Code'((Fix)) range Fix .. Dec loop ...
  -- qualification unnecessary
for J in Code'((Fix)) .. Dec loop ...
  -- qualification unnecessary for Dec

Dozen'((1 | 3 | 5 | 7 => 2, others => 0)) -- see 4.6
```

Wording Changes from Ada 2005

{AI05-0003-1} Added a definition of the nominal subtype of a qualified_expression.

4.8 Allocators

The evaluation of an allocator creates an object and yields an access value that designates the object.

Syntax

```ada
{AI05-0111-3} allocator ::= new [subpool_specification] subtype_indication
  | new [subpool_specification] qualified_expression

{AI05-0111-3} subpool_specification ::= (subpool_handle_name)

{AI05-0104-1} For an allocator with a subtype_indication, the subtype_indication shall not specify
  a null_exclusion.
{AI05-0111-3} Reason: Such an uninitialized allocator would necessarily raise Constraint_Error, as the default value is null. Also
  note that the syntax does not allow a null_exclusion in an initialized allocator, so it makes sense to make the
  uninitialized case illegal as well.
```

Name Resolution Rules

{8652/0010} {AI95-00127-01} {AI05-0111-3} {AI05-0269-1} The expected type for an allocator shall be a single access-to-object type with
  whose designated type D such that either D covers the type determined by the subtype_mark of the subtype_indication or qualified_expression, or the expected
type is anonymous and the determined type is D.Class. A subpool_handle_name is expected to be of any
type descended from Subpool_Handle, which is the type used to identify a subpool, declared in package
System.Storage_Pools.Subpools (see 13.11.4).

Discussion: See 8.6, “The Context of Overload Resolution” for the meaning of “shall be a single ... type whose ...

Ramification: {8652/0010} {AI95-00127-01} An allocator is allowed as a controlling parameter of a dispatching call
(see 3.9.2).

Legality Rules

An initialized allocator is an allocator with a qualified_expression. An uninitialized allocator is one with
a subtype_indication. In the subtype_indication of an uninitialized allocator, a constraint is permitted
only if the subtype_mark denotes an [unconstrained] composite subtype; if there is no constraint, then
the subtype_mark shall denote a definite subtype.

Ramification: For example, ... new S'Class ... (with no initialization expression) is illegal, but ... new S'Class'(X) ... is
legal, and takes its tag and constraints from the initial value X. (Note that the former case cannot have a constraint.)
\[\text{AI05-0111-3}\] If a `subpool_specification` is given, the type of the storage pool of the access type shall be a descendant of `Root_Storage_Pool_With_Subpools`.

\[\text{AI95-00344-01}\] If the designated type of the type of the `allocator` is class-wide, the accessibility level of the type determined by the `subtype_indication` or qualified expression shall not be statically deeper than that of the type of the `allocator`.

**Reason:** This prevents the allocated object from outliving its type.

\[\text{AI05-00416-01}\] If the `subtype` determined by the `subtype_indication` or qualified expression designated subtype of the type of the `allocator` has one or more unconstrained access discriminants, then the accessibility level of the anonymous access type of each access discriminant, as determined by the `subtype_indication` or qualified expression of the `allocator`, shall not be statically deeper than that of the type of the `allocator` (see 3.10.2).

**Reason:** This prevents the allocated object from outliving its discriminants.

\[\text{AI95-00366-01}\] An `allocator` shall not be of an access type for which the `Storage_Size` has been specified by a static expression with value zero or is defined by the language to be zero. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. This rule does not apply in the body of a generic unit or within a body declared within the declarative region of a generic unit, if the type of the `allocator` is a descendant of a formal access type declared within the formal part of the generic unit.

**Reason:** An `allocator` for an access type that has `Storage_Size` specified to be zero is required to raise `Storage_Error` anyway. It's better to detect the error at compile-time, as the `allocator` might be executed infrequently. This also simplifies the rules for Pure units, where we do not want to allow any allocators for library-level access types, as they would represent state.

\[\text{AI05-0157-1}\] We don't need a special rule to cover generic formals (unlike many other similar Legality Rules). There are only two cases of interest. For formal access types, the `Storage_Size` property is not known in the generic, and surely isn't static, so this Legality Rule can never apply. For a formal derived type, this Legality Rule can only be triggered by a parent type having one of the appropriate properties. But `Storage_Size` can never be specified for a derived access type, so it always has the same value for all child types; additionally, a type derived from a remote access type (which has `Storage_Size` defined to be zero) is also a remote access type. That means that any actual that would match the formal derived type necessarily has the same `Storage_Size` properties, so it is harmless (and preferable) to check them in the body - they are always known in that case. For other formal types, `allocator`s are not allowed, so we don't need to consider them. So we don't need an assume-the-best rule here. The last sentence covers the case of children of generics, and formal access types of formal packages of the generic unit.

\[\text{AI05-0052-1}\] If the designated type of the type of the `allocator` is limited, then the `allocator` shall not be used to define the value of an access discriminant, unless the discriminated type is immutably limited (see 7.5).

**Reason:** Because coextensions work very much like parts, we don't want users creating limited coextensions for nonlimited types. This would be similar to extending a nonlimited type with a limited component. We check this on the `allocator`. Note that there is an asymmetry in what types are considered limited; this is required to preserve privacy. We have to assume that the designated type might be limited as soon as we see a limited partial view, but we want to ensure that the containing object is of a type that is always limited.

\[\text{AI05-0052-1}\] In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

**Discussion:** This applies to all of the Legality Rules of this subclause.

**Static Semantics**

\[\text{AI95-00363-01}\] If the designated type of the type of the `allocator` is elementary, then the subtype of the created object is the designated subtype. If the designated type is composite, then the `subtype` of the created object is the designated subtype when the designated subtype is constrained or
there is an ancestor of the designated type that has a constrained partial view of the designated type that is constrained; otherwise, the created object is always constrained; if the designated subtype is constrained, then it provides the constraint of the created object; otherwise, the object is constrained by its initial value [(even if the designated subtype is unconstrained with defaults)].

Discussion: See A183-00331.

Reason: A195-00363-01] All objects created by an allocator are aliased, and most aliased composite objects need to be constrained so that access subtypes work reasonably. Problematic access subtypes are prohibited for types with a constrained partial view.

Discussion: A195-00363-01] If there is a constrained partial view of the type, this allows the objects to be unconstrained. This eliminates privacy breaking (we don't want the objects to act differently simply because they're allocated). Such a created object is effectively constrained by its initial value if the access type is an access-to-constant type, or the designated type is limited (in all views), but we don't need to state that here. It is implicit in other rules. Note, however, that a value of an access-to-constant type can designate a variable object via 'Access or conversion, and the variable object might be assigned by some other access path, and that assignment might alter the discriminants.

Dynamic Semantics

7/2] A195-00373-01] For the evaluation of an initialized allocator, the elaboration of the subtype indication or the evaluation of the qualified expression is performed first. An object of the designated type is created and the value of the qualified expression is converted to the designated subtype and assigned to the object.

Ramification: The conversion might raise Constraint_Error.

For the evaluation of an uninitialized allocator, the elaboration of the subtype indication is performed first. Then:

9/2] A195-00373-01] If the designated type is elementary, an object of the designated subtype is created and any implicit initial value is assigned;

10/2] A195-00373-01] If the designated type is composite, an object of the designated type is created with tag, if any, determined by the subtype_mark of the subtype indication. This object is then initialized by default (see 3.3.1) using any per-object constraints on subcomponents are elaborated (see 3.8) and any implicit initial values for the subcomponents of the object are obtained as determined by the subtype indication to determine its nominal subtype and assigned to the corresponding subcomponents. A check is made that the value of the object belongs to the designated subtype. Constraint_Error is raised if this check fails. This check and the initialization of the object are performed in an arbitrary order.

Discussion: A183-00150.

A195-00344-01] A195-00416-01] A1105-00234-1] A1105-0051-1] A1105-0234-1] For any allocator, if the designated type of the type of the allocator is class-wide, then a check is made that the master accessibility level of the type determined by the subtype indication, or by the tag of the value of the qualified expression, includes the elaboration not deeper than that of the type of the allocator. If any part of the subtype determined by the subtype indication or qualified expression designated subtype of the allocator (or by the tag of the value if the type of the qualified expression is class-wide) has one or more unconstrained access discriminants, then a check is made that the accessibility level of the anonymous access type of each access discriminant is not deeper than that of the type of the allocator. Program_Error is raised if either such check fails.

Reason: A195-00344-01] A1105-00234-1] The master accessibility check on class-wide types prevents the allocated object from outliving its type. We need the run-time check in instance bodies, or when the type of the qualified expression is class-wide (other cases are statically detected).

A1105-0024-1] We can't use the normal accessibility level “deeper than” check here because we may have “incomparable” levels if the appropriate master and the type declaration belong to two different tasks. This can happen when checking the master of the tag for an allocator initialized by a parameter passed in to an accept statement, if the type of the allocator is an access type declared in the enclosing task body. For example:
task body TT is
  type Acc_TC is access T'Class;
  P : Acc_TC;
begin
  accept E(X : T'Class) do
    P := new T'Class'(X);
    -- Master check on tag of X.
    -- Can't use "accessibility levels" since they might be incomparable.
    -- Must revert to checking that the master of the type identified by
    -- X'tag includes the elaboration of Acc_TC, so it is sure to outlive it.
  end E;
{AI95-00416-01} The accessibility check on access discriminants prevents the allocated object from outliving its discriminants.

{AI95-00280-01} If the object to be created by an allocator has a controlled or protected part, and the finalization of the collection of the type of the allocator (see 7.6.1) has started, Program_Error is raised.

  Reason: If the object has a controlled or protected part, its finalization is likely to be nontrivial. If the allocation was allowed, we could not know whether the finalization would actually be performed. That would be dangerous to otherwise safe abstractions, so we mandate a check here. On the other hand, if the finalization of the object will be trivial, we do not require (but allow) the check, as no real harm could come from late allocation.

  Discussion: This check can only fail if an allocator is evaluated in code reached from a Finalize routine for a type declared in the same master. That's highly unlikely; Finalize routines are much more likely to be deallocating objects than allocating them.

{AI95-00280-01} If the object to be created by an allocator contains any tasks, and the master of the type of the allocator is completed, and all of the dependent tasks of the master are terminated (see 9.3), then Program_Error is raised.

  Reason: A task created after waiting for tasks has finished could depend on freed data structures, and certainly would never be awaited.

{AI05-0111-3} If the allocator includes a subpool handle name, Constraint_Error is raised if the subpool handle is null. Program_Error is raised if the subpool does not belong (see 13.11.4) to the storage pool of the access type of the allocator.

  Implementation Note: This can be implemented by comparing the result of Pool_of_Subpool to a reference to the storage pool object. Pool_of_Subpool's parameter is not null, so the check for null falls out naturally.

  Reason: This detects cases where the subpool belongs to another pool, or to no pool at all. This includes detecting dangling subpool handles so long as the subpool object (the object designated by the handle) still exists. (If the subpool object has been deallocated, execution is erroneous; it is likely that this check will still detect the problem, but there cannot be a guarantee.)

[If the created object contains any tasks, they are activated (see 9.2).] Finally, an access value that designates the created object is returned.

Bounded (Run-Time) Errors

{AI95-00280-01} It is a bounded error if the finalization of the collection of the type (see 7.6.1) of the allocator has started. If the error is detected, Program_Error is raised. Otherwise, the allocation proceeds normally.

  Discussion: This check is required in some cases; see above.

NOTES
24 Allocators cannot create objects of an abstract type. See 3.9.3.
25 If any part of the created object is controlled, the initialization includes calls on corresponding Initialize or Adjust procedures. See 7.6.
26 As explained in 13.11, “Storage Management”, the storage for an object allocated by an allocator comes from a storage pool (possibly user defined). The exception Storage_Error is raised by an allocator if there is not enough storage. Instances of Unchecked_Deallocation may be used to explicitly reclaim storage.
27 {AI05-0229-1} Implementations are permitted, but not required, to provide garbage collection (see 13.11.3).
Ramification: Note that in an allocator, the exception Constraint_Error can be raised by the evaluation of the qualified_expression, by the elaboration of the subtype_indication, or by the initialization.

Discussion: By default, the implementation provides the storage pool. The user may exercise more control over storage management by associating a user-defined pool with an access type.

Examples

Examples of allocators:

17

new Cell'(0, null, null) -- initialized explicitly, see 3.10.1
new Cell'(Value => 0, Succ => null, Pred => null) -- initialized explicitly
new Cell -- not initialized
new Matrix(1..10, 1..20) -- the bounds only are given
new Matrix'(1..10 => (1..20 => 0.0)) -- initialized explicitly
new Buffer(100) -- the discriminant only is given
new Buffer'(Size => 80, Pos => 0, Value => (1..80 => 'A')) -- initialized explicitly
Expr_Ptr'(new Literal) -- allocator for access-to-class-wide type, see 3.9.1
Expr_Ptr'(new Literal'(Expression with 3.5)) -- initialized explicitly

Incompatibilities With Ada 83

The subtype_indication of an uninitialized allocator may not have an explicit constraint if the designated type is an access type. In Ada 83, this was permitted even though the constraint had no effect on the subtype of the created object.

Extensions to Ada 83

Allocators creating objects of type \( T \) are now overloaded on access types designating \( T \) Class and all class-wide types that cover \( T \).

Implicit array subtype conversion (sliding) is now performed as part of an initialized allocator.

Wording Changes from Ada 83

We have used a new organization, inspired by the ACID document, that makes it clearer what is the subtype of the created object, and what subtype conversions take place.

Discussion of storage management issues, such as garbage collection and the raising of Storage_Error, has been moved to 13.11, “Storage Management”.

Inconsistencies With Ada 95

\{AI95-00363-01\} If the designated type has a constrained partial view, the allocated object can be unconstrained. This might cause the object to take up a different amount of memory, and might cause the operations to work where they previously would have raised Constraint_Error. It's unlikely that the latter would actually matter in a real program (Constraint_Error usually indicates a bug that would be fixed, not left in a program.) The former might cause Storage_Error to be raised at a different time than in an Ada 95 program.

Incompatibilities With Ada 95

\{AI95-00366-01\} An allocator for an access type that has Storage_Size specified to be zero is now illegal. Ada 95 allowed the allocator, but it had to raise Storage_Error if executed. The primary impact of this change should be to detect bugs.

Extensions to Ada 95

\{8652/0010\} \{AI95-00127-01\} Corrigendum: An allocator can be a controlling parameter of a dispatching call. This was an oversight in Ada 95.

\{AI95-00287-01\} Initialized allocators are allowed when the designated type is limited.

Wording Changes from Ada 95

\{8652/0002\} \{AI95-00171-01\} Corrigendum: Clarified the elaboration of per-object constraints for an uninitialized allocator.
Program_Error is now raised if the allocator occurs after the finalization of the collection or the waiting for tasks. This is not listed as an incompatibility as the Ada 95 behavior was unspecified, and Ada 95 implementations tend to generate programs that crash in this case.

Added accessibility checks to class-wide allocators. These checks could not fail in Ada 95 (as all of the designated types had to be declared at the same level, so the access type would necessarily have been at the same level or more nested than the type of allocated object).

Revised the description of evaluation of uninitialized allocators to use “initialized by default” so that the ordering requirements are the same for all kinds of objects that are default-initialized.

Added accessibility checks to access discriminants of allocators. These checks could not fail in Ada 95 as the discriminants always have the accessibility of the object.

Incompatibilities With Ada 2005

Correction: Added a rule to prevent limited coextensions of nonlimited types. Allowing this would have far-reaching implementation costs. Because of those costs, it seems unlikely that any implementation ever supported it properly and thus it is unlikely that any existing code depends on this capability.

Correction: Added a rule to make null exclusions illegal for uninitialized allocators, as such an allocator would always raise Constraint_Error. Programs that depend on the unconditional raising of a predefined exception should be very rare.

Extensions to Ada 2005

Subpool handles (see 13.11.4) can be specified in an allocator.

Wording Changes from Ada 2005

Correction: Corrected the master check for tags since the masters may be for different tasks and thus incomparable.

Correction: Corrected the rules for when a designated object is constrained by its initial value so that types derived from a partial view are handled properly.

Correction: Corrected the accessibility check for access discriminants so that it does not depend on the designated type (which might not have discriminants when the allocated type does).

4.9 Static Expressions and Static Subtypes

Certain expressions of a scalar or string type are defined to be static. Similarly, certain discrete ranges are defined to be static, and certain scalar and string subtypes are defined to be static subtypes. [Static means determinable at compile time, using the declared properties or values of the program entities.]

Discussion: As opposed to more elaborate data flow analysis, etc.

Language Design Principles

For an expression to be static, it has to be calculable at compile time.

Only scalar and string expressions are static.

To be static, an expression cannot have any nonscalar, nonstring subexpressions (though it can have nonscalar constituent names). A static scalar expression cannot have any nonscalar subexpressions. There is one exception—a membership test for a string subtype can be static, and the result is scalar, even though a subexpression is nonscalar.

The rules for evaluating static expressions are designed to maximize portability of static calculations.

A static expression is [a scalar or string expression that is] one of the following:

• a numeric_literal;
  Ramification: A numeric_literal is always a static expression, even if its expected type is not that of a static subtype. However, if its value is explicitly converted to, or qualified by, a nonstatic subtype, the resulting expression is nonstatic.

• a string_literal of a static string subtype;
Ramification: That is, the constrained subtype defined by the index range of the string is static. Note that elementary values don't generally have subtypes, while composite values do (since the bounds or discriminants are inherent in the value).

- a name that denotes the declaration of a named number or a static constant;

Ramification: Note that enumeration literals are covered by the function_call case.

- a function_call whose function_name or function_prefix statically denotes a static function, and whose actual parameters, if any (whether given explicitly or by default), are all static expressions;

Ramification: This includes uses of operators that are equivalent to function_calls.

- an attribute_reference that denotes a scalar value, and whose prefix denotes a static scalar subtype;

Ramification: Note that this does not include the case of an attribute that is a function; a reference to such an attribute is not even an expression. See above for function calls.

An implementation may define the staticness and other properties of implementation-defined attributes.

- an attribute_reference whose prefix statically denotes a statically constrained array object or array subtype, and whose attribute_designator is First, Last, or Length, with an optional dimension;

- a type_conversion whose subtype_mark denotes a static scalar subtype, and whose operand is a static expression;

- a qualified_expression whose subtype_mark denotes a static [(scalar or string)] subtype, and whose operand is a static expression;

Ramification: This rules out the subtype_mark 'aggregate case.

Reason: Adding qualification to an expression shouldn't make it nonstatic, even for strings.

- {AI05-0158-1} {AI05-0269-1} a membership test whose simple_expression is a static expression, and whose membership_choice_list consists only of membership_choices that are either static_choice_expressions, static ranges, or subtype_marks that denote range is a static range or whose subtype_mark denotes a static [(scalar or string)] subtype;

Reason: Clearly, we should allow membership tests in exactly the same cases where we allow qualified_expressions.

- a short-circuit control form both of whose relations are static expressions;

- {AI05-0147-1} {AI05-0188-1} a conditional_expression all of whose conditions, selecting_expressions, and dependent_expressions are static expressions;

- a static expression enclosed in parentheses.

Discussion: Informally, we talk about a static value. When we do, we mean a value specified by a static expression.

Ramification: The language requires a static expression in a number_declaration, a numeric type definition, a discrete_choice (sometimes), certain representation items, an attribute_designator, and when specifying the value of a discriminant governing a variant_part in a record_aggregate or extension_aggregate.

A name statically denotes an entity if it denotes the entity and:

- It is a direct_name, expanded name, or character_literal, and it denotes a declaration other than a renaming_declaration; or

- It is an attribute_reference whose prefix statically denotes some entity; or

- It denotes a renaming_declaration with a name that statically denotes the renamed entity.

Ramification: Selected_components that are not expanded names and indexed_components do not statically denote things.

A static function is one of the following:

Ramification: These are the functions whose calls can be static expressions.
• a predefined operator whose parameter and result types are all scalar types none of which are descendants of formal scalar types;
• a predefined concatenation operator whose result type is a string type;
• an enumeration literal;
• a language-defined attribute that is a function, if the prefix denotes a static scalar subtype, and if the parameter and result types are scalar.

In any case, a generic formal subprogram is not a static function.

A static constant is a constant view declared by a full constant declaration or an object_renaming_-declaration with a static nominal subtype, having a value defined by a static scalar expression or by a static string expression whose value has a length not exceeding the maximum length of a string_literal in the implementation.

Ramification: A deferred constant is not static; the view introduced by the corresponding full constant declaration can be static.

Reason: The reason for restricting the length of static string constants is so that compilers don't have to store giant strings in their symbol tables. Since most string constants will be initialized from string_literals, the length limit seems pretty natural. The reason for avoiding nonstring types is also to save symbol table space. We're trying to keep it cheap and simple (from the implementer's viewpoint), while still allowing, for example, the aspect_definition for a Link_Name aspect name of a pragma Import to contain a concatenation.

The length we're talking about is the maximum number of characters in the value represented by a string_literal, not the number of characters in the source representation; the quotes don't count.

A static range is a range whose bounds are static expressions, [or a range_attribute_reference that is equivalent to such a range.] A static discrete_range is one that is a static range or is a subtype_-indication that defines a static scalar subtype. The base range of a scalar type is a static range, unless the type is a descendant of a formal scalar type.

{AI95-00263-01} {AI05-0153-3} A static subtype is either a static scalar subtype or a static string subtype. A static scalar subtype is an unconstrained scalar subtype whose type is not a descendant of a formal scalar type, or a constrained scalar subtype formed by imposing a compatible static constraint on a static scalar subtype. A static string subtype is an unconstrained string subtype whose index subtype and component subtype are static (and whose type is not a descendant of a formal array type), or a constrained string subtype formed by imposing a compatible static constraint on a static string subtype. In any case, the subtype of a generic formal object of mode in out, and the result subtype of a generic formal function, are not static. Also, a subtype is not static if any Dynamic_Predicate specifications apply to it.

Ramification: String subtypes are the only composite subtypes that can be static.

Reason: The part about generic formal objects of mode in out is necessary because the subtype of the formal is not required to have anything to do with the subtype of the actual. For example:

```
subtype Int10 is Integer range 1..10;
generic
  F : in out Int10;
procedure G;
procedure G is
begin
  case F is
    when 1..10 => null;
    -- Illegal!
  end case;
end G;
X : Integer range 1..20;
procedure I is new G(F => X); -- OK.
```

The case_statement is illegal, because the subtype of F is not static, so the choices have to cover all values of Integer, not just those in the range 1..10. A similar issue arises for generic formal functions, now that function calls are object names.
The different kinds of static constraint are defined as follows:

- A null constraint is always static;
- A scalar constraint is static if it has no range_constraint, or one with a static range;
- An index constraint is static if each discrete_range is static, and each index subtype of the corresponding array type is static;
- A discriminant constraint is static if each expression of the constraint is static, and the subtype of each discriminant is static.

\{AI95-00311-01\} In any case, the constraint of the first subtype of a scalar formal type is neither static nor null.

A subtype is statically constrained if it is constrained, and its constraint is static. An object is statically constrained if its nominal subtype is statically constrained, or if it is a static string constant.

**Legality Rules**

\{AI05-0147-1\} An expression is statically unevaluated if it is part of:

- \{AI05-0147-1\} the right operand of a static short-circuit control form whose value is determined by its left operand; or
- \{AI05-0188-1\} a dependent expression of an if_expression whose associated condition is static and equals False; or
- \{AI05-0147-1\} \{AI05-0188-1\} a condition or dependent expression of an if_expression where the condition corresponding to at least one preceding dependent expression of the if_expression is static and equals True; or

**Reason:** We need this bullet so that only a single dependent expression is evaluated in a static if_expression if there is more than one condition that evaluates to True. The part about conditions makes

```
if N = 0 then Min elsif 10_000/N > Min then 10_000/N else Min
```

legal if N and Min are static and N = 0.

**Discussion:** \{AI05-0147-1\} \{AI05-0188-1\} We need the "of the if_expression" here so there is no confusion for nested if_expressions; this rule only applies to the conditions and dependent expressions of a single if_expression. Similar reasoning applies to the "of a case_expression" of the last bullet.

- \{AI05-0188-1\} \{AI05-0269-1\} a dependent expression of a case_expression whose selecting expression is static and whose value is not covered by the corresponding discrete_choice_list; or
- \{AI05-0158-1\} a choice_expression (or a simple expression of a range that occurs as a membership_choice of a membership_choice_list) of a static membership test that is preceded in the enclosing membership_choice_list by another item whose individual membership test (see 4.5.2) statically yields True.

\{AI05-0147-1\} A static expression is evaluated at compile time except when it is statically unevaluated part of the right operand of a static short-circuit control form whose value is determined by its left operand. The compile-time evaluation of a static expression is performed exactly, without performing Overflow_Checks. For a static expression that is evaluated:

- \{AI05-0262-1\} The expression is illegal if its evaluation fails a language-defined check other than Overflow_Check. For the purposes of this evaluation, the assertion policy is assumed to be Check.

**Reason:** \{AI05-0262-1\} Assertion policies can control whether checks are made, but we don't want assertion policies to affect legality. For Ada 2012, subtype predicates are the only checks controlled by the assertion policy that can appear in static expressions.
• \{AI95-00269-01\} If the expression is not part of a larger static expression and the expression is expected to be of a single specific type, then its value shall be within the base range of its expected type. Otherwise, the value may be arbitrarily large or small.

  Ramification: \{AI95-00269-01\} If the expression is expected to be of a universal type, or of “any integer type”, there are no limits on the value of the expression.

• \{AI95-00269-01\} If the expression is of type \texttt{universal_real} and its expected type is a decimal fixed point type, then its value shall be a multiple of the \texttt{small} of the decimal type. This restriction does not apply if the expected type is a descendant of a formal scalar type (or a corresponding actual type in an instance).

  Ramification: This means that a \texttt{numeric_literal} for a decimal type cannot have “extra” significant digits.

  \texttt{Reason}: \{AI95-00269-01\} The \texttt{small} is not known for a generic formal type, so we have to exclude formal types from this check.

\{AI95-00269-01\} In addition to the places where Legality Rules normally apply (see 12.3), the above restrictions also apply in the private part of an instance of a generic unit. The last two restrictions above do not apply if the expected type is a descendant of a formal scalar type (or a corresponding actual type in an instance).

  Discussion: Values outside the base range are not permitted when crossing from the “static” domain to the “dynamic” domain. This rule is designed to enhance portability of programs containing static expressions. Note that this rule applies to the exact value, not the value after any rounding or truncation. (See below for the rounding and truncation requirements.)

  Short-circuit control forms are a special case:

  \begin{verbatim}
  N: constant := 0.0;
  X: constant Boolean := (N = 0.0) or else (1.0/N > 0.5); -- Static.
  \end{verbatim}

  The declaration of X is legal, since the divide-by-zero part of the expression is not evaluated. X is a static constant equal to True.

  Ramification: \{AI95-00269-01\} There is no requirement to recheck these rules in an instance; the base range check will generally be performed at run-time anyway.

Implementation Requirements

\{AI95-00268-01\} \{AI95-00269-01\} For a real static expression that is not part of a larger static expression, and whose expected type is not a descendant of a formal \texttt{scalar} type, the implementation shall round or truncate the value (according to the Machine Rounds attribute of the expected type) to the nearest machine number of the expected type; if the value is exactly half-way between two machine numbers, \texttt{any} rounding shall be performed \texttt{is implementation-defined} away from zero. If the expected type is a descendant of a formal \texttt{scalar}-type, or if the static expression appears in the body of an instance of a generic unit and the corresponding expression is nonstatic in the corresponding generic body, then no special rounding or truncating is required — normal accuracy rules apply (see Annex G).

  Implementation defined: Rounding of real static expressions which are exactly half-way between two machine numbers.

  Reason: \{AI95-00268-01\} Discarding extended precision enhances portability by ensuring that the value of a static constant of a real type is always a machine number of the type. Deterministic rounding of exact halves also enhances portability.

  When the expected type is a descendant of a formal floating point type, extended precision (beyond that of the machine numbers) can be retained when evaluating a static expression, to ease code sharing for generic instantiations. For similar reasons, normal (nondeterministic) rounding or truncating rules apply for descendants of a formal fixed point type.

  \{AI95-00268-01\} There is no requirement for exact evaluation or special rounding in an instance body (unless the expression is static in the generic body). This eliminates a potential contract issue where the exact value of a static expression depends on the actual parameters (which could then affect the legality of other code).

  Implementation Note: Note that the implementation of static expressions has to keep track of plus and minus zero for a type whose \texttt{Signed_Zeros} attribute is True.
Note that the only machine numbers of a fixed point type are the multiples of the small, so a static conversion to a fixed-point type, or division by an integer, must do truncation to a multiple of small. It is not correct for the implementation to do all static calculations in infinite precision.

**Implementation Advice**

For a real static expression that is not part of a larger static expression, and whose expected type is not a descendant of a formal type, the rounding should be the same as the default rounding for the target system.

**Implementation Advice:** A real static expression with a nonformal type that is not part of a larger static expression should be rounded the same as the target system.

### NOTES

38. An expression can be static even if it occurs in a context where staticness is not required.

38.a Ramification: For example:

38.b

38.c

38.d The following kinds of expressions are never static: explicit_dereference, indexed_component, slice, null, aggregate, allocator.

39 A static (or run-time) type_conversion from a real type to an integer type performs rounding. If the operand value is exactly half-way between two integers, the rounding is performed away from zero.

39.a Reason: We specify this for portability. The reason for not choosing round-to-nearest-even, for example, is that this method is easier to undo.

39.b Ramification: The attribute Truncation (see A.5.3) can be used to perform a (static) truncation prior to conversion, to prevent rounding.

39.c Implementation Note: The value of the literal 0E999999999999999999999999999999999999999999999 is zero. The implementation must take care to evaluate such literals properly.

### Examples of static expressions:

41

\[
\begin{align*}
1 + 1 & \rightarrow 2 \\
\text{abs}(-10) \times 3 & \rightarrow 30 \\
\text{Kilo} : \text{constant} & := 1000; \\
\text{Mega} : \text{constant} & := \text{Kilo} \times \text{Kilo}; \quad \rightarrow 1\_000\_000 \\
\text{Long} : \text{constant} & := \text{Float'}\text{Digits}\times 2; \\
\text{Half_Pi} : \text{constant} & := \text{Pi}/2; \quad \rightarrow \text{see 3.3.2} \\
\text{Deg_TO_Rad} : \text{constant} & := \text{Half_Pi}/90; \\
\text{Rad_TO_Deg} : \text{constant} & := 1.0/\text{Deg_TO_Rad}; \quad \rightarrow \text{equivalent to } 1.0/(3.14159_265362/90)
\end{align*}
\]

### Extensions to Ada 83

The rules for static expressions and static subtypes are generalized to allow more kinds of compile-time-known expressions to be used where compile-time-known values are required, as follows:

- Membership tests and short-circuit control forms may appear in a static expression.
- The bounds and length of statically constrained array objects or subtypes are static.
- The Range attribute of a statically constrained array subtype or object gives a static range.
- A type_conversion is static if the subtype_mark denotes a static scalar subtype and the operand is a static expression.
- All numeric literals are now static, even if the expected type is a formal scalar type. This is useful in case_statements and variant_parts, which both now allow a value of a formal scalar type to control the selection, to ease conversion of a package into a generic package. Similarly, named array aggregates are also permitted for array types with an index type that is a formal scalar type.
- The rules for the evaluation of static expressions are revised to require exact evaluation at compile time, and force a machine number result when crossing from the static realm to the dynamic realm, to enhance portability and predictability. Exact evaluation is not required for descendants of a formal scalar type, to simplify generic code sharing and to avoid generic contract model problems.
Static expressions are legal even if an intermediate in the expression goes outside the base range of the type. Therefore, the following will succeed in Ada 95, whereas it might raise an exception in Ada 83:

```ada
type Short_Int is range -32_768 .. 32_767;
I : Short_Int := -32_768;
```

This might raise an exception in Ada 83 because "32_768" is out of range, even though "–32_768" is not. In Ada 95, this will always succeed.

Certain expressions involving string operations (in particular concatenation and membership tests) are considered static in Ada 95.

The reason for this change is to simplify the rule requiring compile-time-known string expressions as the link name in an interfacing pragma, and to simplify the preelaborability rules.

### Incompatibilities With Ada 83

An Ada 83 program that uses an out-of-range static value is illegal in Ada 95, unless the expression is part of a larger static expression, or the expression is not evaluated due to being on the right-hand side of a short-circuit control form.

### Wording Changes from Ada 83

{[AI05-0299-1]} This subclause (and 4.5.5, “Multiplying Operators”) subsumes the RM83 section on Universal Expressions.

The existence of static string expressions necessitated changing the definition of static subtype to include string subtypes. Most occurrences of "static subtype" have been changed to "static scalar subtype", in order to preserve the effect of the Ada 83 rules. This has the added benefit of clarifying the difference between "static subtype" and "statically constrained subtype", which has been a source of confusion. In cases where we allow static string subtypes, we explicitly use phrases like "static string subtype" or "static (scalar or string) subtype", in order to clarify the meaning for those who have gotten used to the Ada 83 terminology.

In Ada 83, an expression was considered nonstatic if it raised an exception. Thus, for example:

```ada
Bad: constant := 1/0; -- Illegal!
```

was illegal because 1/0 was not static. In Ada 95, the above example is still illegal, but for a different reason: 1/0 is static, but there's a separate rule forbidding the exception raising.

### Inconsistencies With Ada 95

{[AI95-00268-01]} Amendment Correction: Rounding of static real expressions is implementation-defined in Ada 2005, while it was specified as away from zero in (original) Ada 95. This could make subtle differences in programs. However, the original Ada 95 rule required rounding that (probably) differed from the target processor, thus creating anomalies where the value of a static expression was required to be different than the same expression evaluated at runtime.

### Wording Changes from Ada 95

{[AI95-00263-01]} {[AI95-00268-01]} The Ada 95 wording that defined static subtypes unintentionally failed to exclude formal derived types that happen to be scalar (these aren't formal scalar types); and had a parenthetical remark excluding formal string types - but that was neither necessary nor parenthetical (it didn't follow from other wording). This issue also applies to the rounding rules for real static expressions.

{[AI95-00269-01]} Ada 95 didn't clearly define the bounds of a value of a static expression for universal types and for "any integer/float/fixed type". We also make it clear that we do not intend exact evaluation of static expressions in an instance body if the expressions aren't static in the generic body.

{[AI95-00311-01]} We clarify that the first subtype of a scalar formal type has a nonstatic, nonnull constraint.

### Wording Changes from Ada 2005

{[AI05-0147-1]} {[AI05-0188-1]} Added wording to define staticness and the lack of evaluation for if_expressions and case_expressions. These are new and defined elsewhere.

{[AI05-0153-3]} Added wording to prevent subtypes that have dynamic predicates (see 3.2.4) from being static.

{[AI05-0158-1]} Revised wording for membership tests to allow for the new possibilities allowed by the membership_choice_list.
4.9.1  Statically Matching Constraints and Subtypes

Static Semantics

{AI95-00311-01} A constraint *statically matches* another constraint if:

- both are null constraints;
- both are static and have equal corresponding bounds or discriminant values;
- both are nonstatic and result from the same elaboration of a constraint of a subtype_indication or the same evaluation of a range of a discrete_subtype_definition; or
- both are nonstatic and come from the same formal_type_declaration.

{AI95-00231-01} {AI95-00254-01} {AI05-0153-3} A subtype *statically matches* another subtype of the same type if they have statically matching constraints, all predicate specifications that apply to them come from the same declarations, and, for access subtypes, either both or neither exclude null. Two anonymous access-to-object subtypes statically match if their designated subtypes statically match, and either both or neither exclude null, and either both or neither are access-to-constant. Two anonymous access-to-subprogram subtypes statically match if their designated profiles are subtype conformant, and either both or neither exclude null.

Ramification: Statically matching constraints and subtypes are the basis for subtype conformance of profiles (see 6.3.1).

Reason: Even though anonymous access types always represent different types, they can statically match. That's important so that they can be used widely. For instance, if this wasn't true, access parameters and access discriminants could never conform, so they couldn't be used in separate specifications.

Two ranges of the same type *statically match* if both result from the same evaluation of a range, or if both are static and have equal corresponding bounds.

Ramification: The notion of static matching of ranges is used in 12.5.3, “Formal Array Types”; the index ranges of formal and actual constrained array subtypes have to statically match.

Discussion: Static compatibility is required when constraining a parent subtype with a discriminant from a new discriminant_part. See 3.7. Static compatibility is also used in matching generic formal derived types.

Note that statically compatible with a subtype does not imply compatible with a type. It is OK since the terms are used in different contexts.

Two statically matching subtypes are statically compatible with each other. In addition, a subtype S1 is statically compatible with a subtype S2 if:

- the constraint of S1 is statically compatible with S2, and

- {AI05-0086-1} if S2 excludes null, so does S1, and

- either:
  - all predicate specifications that apply to S2 apply also to S1, or

5/3 {AI05-0153-3}
• both subtypes are static, every value that satisfies the predicate of \( S_1 \) also satisfies the predicate of \( S_2 \), and it is not the case that both types each have at least one applicable predicate specification, predicate checks are enabled (see 11.4.2) for \( S_2 \), and predicate checks are not enabled for \( S_1 \).

Wording Changes from Ada 83

This subclause is new to Ada 95.

Wording Changes from Ada 95

\{AI95-00231-01\} \{AI95-00254-01\} Added static matching rules for null exclusions and anonymous access-to-subprogram types; both of these are new.

\{AI95-00311-01\} We clarify that the constraint of the first subtype of a scalar formal type statically matches itself.

Incompatibilities With Ada 2005

\{AI05-0086-1\} \textbf{Correction:} Updated the statically compatible rules to take null exclusions into account. This is technically incompatible, as it could cause a legal Ada 2005 program to be rejected; however, such a program violates the intent of the rules (for instance, 3.7(15)) and this probably will simply detect bugs.

Wording Changes from Ada 2005

\{AI05-0153-3\} \{AI05-0290-1\} Modified static matching and static compatibility to take predicate aspects (see 3.2.4) into account.
5 Statements

[A statement defines an action to be performed upon its execution.]

\{AI95-00318-02\} \{AI05-0299-1\} [This \textit{clausesection} describes the general rules applicable to all statements. Some statements are discussed in later \textit{clausesections}: Procedure\_call\_statements and return\_statements \textit{return_statements} are described in 6, “Subprograms”. Entry\_call\_statements, requeue\_statements, delay\_statements, accept\_statements, select\_statements, and abort\_statements are described in 9, “Tasks and Synchronization”. Raise\_statements are described in 11, “Exceptions”, and code\_statements in 13. The remaining forms of statements are presented in this \textit{clausesection}.]

\textit{Wording Changes from Ada 83}

\{AI95-00318-02\} The description of \textit{return_statements \textit{return_statements}} has been moved to 6.5, “Return Statements”, so that it is closer to the description of subprograms.

5.1 Simple and Compound Statements - Sequences of Statements

[A statement is either simple or compound. A simple\_statement encloses no other statement. A compound\_statement can enclose simple\_statements and other compound\_statements.]

\textit{Syntax}

\{AI05-0179-1\} \textit{sequence_of_statements} ::= \textit{statement} \{\textit{statement}\} \{\textit{label}\}

\textit{statement} ::= \{\textit{label}\} \textit{simple_statement} \{\textit{label}\} \textit{compound_statement}

\{AI95-00318-02\} \textit{simple_statement} ::= \textit{null_statement}

\textit{null_statement} ::= \textit{null};

\textit{label} ::= \textit{<<label\_statement\_identifier>>}

\textit{statement\_identifier} ::= \textit{direct\_name}

The \textit{direct\_name} of a \textit{statement\_identifier} shall be an identifier (not an operator\_symbol).

\textit{Name Resolution Rules}

The \textit{direct\_name} of a \textit{statement\_identifier} shall resolve to denote its corresponding implicit declaration (see below).

\textit{Legality Rules}

Distinct identifiers shall be used for all \textit{statement\_identifiers} that appear in the same body, including inner block\_statements but excluding inner program units.
Static Semantics

For each statement_identifier, there is an implicit declaration (with the specified identifier) at the end of the declarative_part of the innermost block_statement or body that encloses the statement_identifier. The implicit declarations occur in the same order as the statement_identifiers occur in the source text. If a usage name denotes such an implicit declaration, the entity it denotes is the label, loop_statement, or block_statement with the given statement_identifier.

Reason: We talk in terms of individual statement_identifiers here rather than in terms of the corresponding statements, since a given statement may have multiple statement_identifiers.

A block_statement that has no explicit declarative_part has an implicit empty declarative_part, so this rule can safely refer to the declarative_part of a block_statement.

The scope of a declaration starts at the place of the declaration itself (see 8.2). In the case of a label, loop, or block name, it follows from this rule that the scope of the implicit declaration starts before the first explicit occurrence of the corresponding name, since this occurrence is either in a statement label, a loop_statement, a block_statement, or a goto_statement. An implicit declaration in a block_statement may hide a declaration given in an outer program unit or block_statement (according to the usual rules of hiding explained in 8.3).

The syntax rule for label uses statement_identifier which is a direct_name (not a defining_identifier), because labels are implicitly declared. The same applies to loop and block names. In other words, the label itself is not the defining occurrence; the implicit declaration is.

We cannot consider the label to be a defining occurrence. An example that can tell the difference is this:

```
declare
  -- Label Foo is implicitly declared here.
begin
  for Foo in ... loop
    ...
  <<Foo>> -- Illegal.
  ...
  end loop;
end;
```

{AI05-0299-1} The label in this example is hidden from itself by the loop parameter with the same name; the example is illegal. We considered creating a new syntactic category name, separate from direct_name and selector_name, for use in the case of statement labels. However, that would confuse the rules in Clause Section 8, so we didn't do it.

{AI05-0179-1} If one or more labels end a sequence_of_statements, an implicit null_statement follows the labels before any following constructs.

Reason: The semantics of a goto_statement is defined in terms of the statement having (following) that label. Thus we ensure that every label has a following statement, which might be implicit.

Dynamic Semantics

The execution of a null_statement has no effect.

{AI95-00318-02} A transfer of control is the run-time action of an exit_statement, return_statement, return_statement, goto_statement, or requeue_statement, selection of a terminate_alternative, raising of an exception, or an abort, which causes the next action performed to be one other than what would normally be expected from the other rules of the language. [As explained in 7.6.1, a transfer of control can cause the execution of constructs to be completed and then left, which may trigger finalization.]

The execution of a sequence_of_statements consists of the execution of the individual statements in succession until the sequence_ is completed.

Ramification: It could be completed by reaching the end of it, or by a transfer of control.

NOTES

1 A statement_identifier that appears immediately within the declarative region of a named loop_statement or an accept_statement is nevertheless implicitly declared immediately within the declarative region of the innermost enclosing body or block_statement; in other words, the expanded name for a named statement is not affected by whether the
statement occurs inside or outside a named loop or an accept_statement — only nesting within block_statement is relevant to the form of its expanded name.

**Discussion:** Each comment in the following example gives the expanded name associated with an entity declared in the task body:

```ada
task body Compute is
begin
  Outer:
    for I in 1..10 loop -- Compute.Outer.I
      Blk:
        declare
          Sum : Integer := 0; -- Compute.Blk.Sum
          begin
              Compute.Ent.I := Compute.Outer.I;
              Inner:
                for J in 1..10 loop -- Compute.Blk.Inner.J
                end loop
              end Ent;
            end Blk;
            end loop Outer;
            Record_Result(Sum);
          end Compute;
```

Examples

**Examples of labeled statements:**

```ada
<<Here>> <<Ici>> <<Aqui>> <<Hier>> null;
<<After>> X := 1;
```

**Extensions to Ada 83**

The requeue_statement is new.

**Wording Changes from Ada 83**

We define the syntactic category statement_identifier to simplify the description. It is used for labels, loop names, and block names. We define the entity associated with the implicit declarations of statement names.

Completion includes completion caused by a transfer of control, although RM83-5.1(6) did not take this view.

**Extensions to Ada 95**

{AI95-00318-02} The extended_return_statement is new (simple_return_statement is merely renamed).

{AI95-0179-1} A label can end a sequence of statements, eliminating the requirement for having an explicit null; statement after an ending label (a common use).

### 5.2 Assignment Statements

[An assignment_statement replaces the current value of a variable with the result of evaluating an expression.]

#### Syntax

```ada
assignment_statement ::= 
  variable_name := expression;
```

The execution of an assignment_statement includes the evaluation of the expression and the assignment of the value of the expression into the target. [An assignment operation (as opposed to an
assignment_statement) is performed in other contexts as well, including object initialization and by-copy parameter passing.] The target of an assignment operation is the view of the object to which a value is being assigned; the target of an assignment_statement is the variable denoted by the variable_name.

Discussion: Don't confuse this notion of the “target” of an assignment with the notion of the “target object” of an entry call or requeue.

Don't confuse the term “assignment operation” with the assignment_statement. The assignment operation is just one part of the execution of an assignment_statement. The assignment operation is also a part of the execution of various other constructs; see 7.6.1, “Completion and Finalization” for a complete list. Note that when we say, “such-and-such is assigned to so-and-so”, we mean that the assignment operation is being applied, and that so-and-so is the target of the assignment operation.

Name Resolution Rules

{AI95-00287-01} The variable_name of an assignment_statement is expected to be of any nonlimited type. The expected type for the expression is the type of the target.

Implementation Note: An assignment_statement as a whole is a “complete context,” so if the variable_name of an assignment_statement is overloaded, the expression can be used to help disambiguate it. For example:

```ada
type P1 is access R1;
type P2 is access R2;
function F return P1;
function F return P2;
X : R1;
begin
  F.all := X;  -- Right hand side helps resolve left hand side
```

Legality Rules

{AI95-00287-01} The target [denoted by the variable_name] shall be a variable of a nonlimited type.

If the target is of a tagged class-wide type TClass, then the expression shall either be dynamically tagged, or of type T and tag-indeterminate (see 3.9.2).

Reason: This is consistent with the general rule that a single dispatching operation shall not have both dynamically tagged and statically tagged operands. Note that for an object initialization (as opposed to the assignment_statement), a statically tagged initialization expression is permitted, since there is no chance for confusion (or Tag_Check failure). Also, in an object initialization, tag-indeterminate expressions of any type covered by TClass would be allowed, but with an assignment_statement, that might not work if the tag of the target was for a type that didn't have one of the dispatching operations in the tag-indeterminate expression.

Dynamic Semantics

For the execution of an assignment_statement, the variable_name and the expression are first evaluated in an arbitrary order.

Ramification: Other rules of the language may require that the bounds of the variable be determined prior to evaluating the expression, but that does not necessarily require evaluation of the variable_name, as pointed out by the ACID.

When the type of the target is class-wide:

- If the expression is tag-indeterminate (see 3.9.2), then the controlling tag value for the expression is the tag of the target;

Ramification: See 3.9.2, “Dispatching Operations of Tagged Types”.

- Otherwise [(the expression is dynamically tagged)], a check is made that the tag of the value of the expression is the same as that of the target; if this check fails, Constraint_Error is raised.

The value of the expression is converted to the subtype of the target. [The conversion might raise an exception (see 4.6).]

Ramification: 4.6, "Type Conversions" defines what actions and checks are associated with subtype conversion. For non-array subtypes, it is just a constraint check presuming the types match. For array subtypes, it checks the lengths
and slides if the target is constrained. “Sliding” means the array doesn't have to have the same bounds, so long as it is
the same length.

In cases involving controlled types, the target is finalized, and an anonymous object might be used as an
intermediate in the assignment, as described in 7.6.1, “Completion and Finalization”. In any case, the
converted value of the expression is then assigned to the target, which consists of the following two steps:

To be honest: 7.6.1 actually says that finalization happens always, but unless controlled types are involved, this
finalization during an assignment statement does nothing.

- The value of the target becomes the converted value.
- \{AI05-0299-1\} If any part of the target is controlled, its value is adjusted as explained in
subclause 7.6.

Ramification: If any parts of the object are controlled, abort is deferred during the assignment operation itself, but not
during the rest of the execution of an assignment statement.

NOTES
2 The tag of an object never changes; in particular, an assignment statement does not change the tag of the target.

This paragraph was deleted \{AI95-00363-01\} The values of the discriminants of an object designated by an access value
cannot be changed (not even by assigning a complete value to the object itself) since such objects are always constrained; however, subcomponents of such objects may be unconstrained.

Ramification: The implicit subtype conversion described above for assignment statements is performed only for the
value of the right-hand side expression as a whole; it is not performed for subcomponents of the value.

The determination of the type of the variable of an assignment statement may require consideration of the expression
if the variable name can be interpreted as the name of a variable designated by the access value returned by a function
call, and similarly, as a component or slice of such a variable (see 8.6, “The Context of Overload Resolution”).

Examples

Examples of assignment statements:

\begin{verbatim}
Value := Max_Value - 1;
Shade := Blue;
Next_Frame(F)(M, N) := 2.5;  -- see 4.1.1
U := Dot_Product(V, W);     -- see 6.3
Writer := (Status => Open, Unit => Printer, Line_Count => 60);  -- see 3.8.1
Next_Car.all := (72074, null);  -- see 3.10.1
\end{verbatim}

Examples involving scalar subtype conversions:

\begin{verbatim}
I, J : Integer range 1 .. 10 := 5;
K : Integer range 1 .. 20 := 15;
...
I := J;  -- identical ranges
K := J;  -- compatible ranges
J := K;  -- will raise Constraint_Error if K > 10
\end{verbatim}

Examples involving array subtype conversions:

\begin{verbatim}
A : String(1 .. 31);
B : String(3 .. 33);
...
A := B;  -- same number of components
A(1 .. 9) := "tar sauce";
A(4 .. 12) := A(1 .. 9);  -- A(1 .. 12) = "tartar sauce"
\end{verbatim}

NOTES
4 Notes on the examples: Assignment statements are allowed even in the case of overlapping slices of the same array,
because the variable name and expression are both evaluated before copying the value into the variable. In the above
example, an implementation yielding A(1 .. 12) = "tartartartar" would be incorrect.
Extensions to Ada 83

We now allow user-defined finalization and value adjustment actions as part of assignment_statements (see 7.6, “Assignment and Finalization”).

Wording Changes from Ada 83

The special case of array assignment is subsumed by the concept of a subtype conversion, which is applied for all kinds of types, not just arrays. For arrays it provides “sliding”. For numeric types it provides conversion of a value of a universal type to the specific type of the target. For other types, it generally has no run-time effect, other than a constraint check.

We now cover in a general way in 3.7.2 the erroneous execution possible due to changing the value of a discriminant when the variable in an assignment_statement is a subcomponent that depends on discriminants.

Incompatibilities With Ada 95

{\textit{AI95-00287-01} The change of the limited check from a resolution rule to a legality rule is not quite upward compatible. For example}

\begin{verbatim}

type AccNonLim is access NonLim;
function Foo (Arg : in Integer) return AccNonLim;
type AccLim is access Lim;
function Foo (Arg : in Integer) return AccLim;
end if;
\end{verbatim}

{\textit{AI05-0147-1} A condition is expected to be of any boolean type. Paragraphs 3 and 4 were deleted.}

5.3 If Statements

[An if_statement selects for execution at most one of the enclosed sequences_of_statements, depending on the (truth) value of one or more corresponding conditions.]

Syntax

\begin{verbatim}

if_statement ::= if condition then sequence_of_statements {elsif condition then sequence_of_statements} [else sequence_of_statements] end if;
\end{verbatim}

\textit{AI05-0147-1 condition ::= boolean_expression}

Name Resolution Rules

\textit{AI05-0147-1} A condition is expected to be of any boolean type.

Dynamic Semantics

\textit{AI05-0264-1} For the execution of an if_statement, the condition specified after if, and any conditions specified after elsif, are evaluated in succession (treating a final else as elsif True then), until one evaluates to True or all conditions are evaluated and yield False. If a condition evaluates to True, then the corresponding sequence_of_statements is executed; otherwise, none of them is executed.

\textit{5.a} Ramification: The part about all evaluating to False can't happen if there is an else, since that is herein considered equivalent to elsif True then.
Examples

Examples of if statements:

if Month = December and Day = 31 then
  Month := January;
  Day := 1;
  Year := Year + 1;
end if;

if Line_Too_Short then
  raise Layout_Error;
elsif Line_Full then
  New_Line;
  Put(Item);
else
  Put(Item);
end if;

if My_Car.Owner.Vehicle /= My_Car then
  -- see 3.10.1
  Report ("Incorrect data");
end if;

Wording Changes from Ada 2005

{AI05-0147-1} Moved definition of condition to 4.5.7 in order to eliminate a forward reference.

5.4 Case Statements

[A case_statement selects for execution one of a number of alternative sequences_of_statements; the
chosen alternative is defined by the value of an expression.]

Syntax

{AI05-0188-1} case_statement ::= case selecting_expression is
  case_statement_alternative
  {case_statement_alternative}
end case;

case_statement_alternative ::= when discrete_choice_list =>
  sequence_of_statements

Name Resolution Rules

{AI05-0188-1} The selecting_expression is expected to be of any discrete type. The expected type for
each discrete_choice is the type of the selecting_expression.

Legality Rules

{AI05-0153-3} The choice_expression, subtype_indication, expression, and range_discrete_ranges
given as discrete_choices of a case_statement shall be static. [A discrete_choice others, if present,
shall appear alone and in the last discrete_choice_list.]

{AI05-0188-1} {AI05-0240-1} The possible values of the selecting_expression shall be covered (see
3.8.1) as follows:

Discussion: {AI05-0240-1} The meaning of "covered" here and in the following rules is that of the term "cover a
value" that is defined in 3.8.1.

• {AI05-0003-1} {AI05-0153-3} {AI05-0188-1} {AI05-0262-1} If the selecting_expression is a
  name [(including a type_conversion, qualified_expression, or a function_call)] having a static
  and constrained nominal subtype, or is a qualified_expression whose subtype_mark denotes a

static and constrained scalar subtype, then each non-others discrete_choice shall cover only values in that subtype that satisfy its predicate (see 3.2.4), and each value of that subtype that satisfies its predicate shall be covered by some discrete_choice [(either explicitly or by others)].

7.a Ramification: Although not official names of objects, a value conversion still has a defined nominal subtype, namely its target subtype. See 4.6.

8/3 • {AI05-0188-1} If the type of the selecting_expression is root_integer, universal_integer, or a descendant of a formal scalar type, then the case_statement shall have an others discrete_choice.

8.a Reason: This is because the base range is implementation defined for root_integer and universal_integer, and not known statically in the case of a formal scalar type.

9/3 • {AI05-0188-1} Otherwise, each value of the base range of the type of the selecting_expression shall be covered [(either explicitly or by others)].

Two distinct discrete_choices of a case_statement shall not cover the same value.

10. Ramification: {AI05-0188-1} The goal of these coverage rules is that any possible value of the selecting_expression of a case_statement should be covered by exactly one discrete_choice of the case_statement, and that this should be checked at compile time. The goal is achieved in most cases, but there are two minor loopholes:

10.b • If the expression reads an object with an invalid representation (e.g. an uninitialized object), then the value can be outside the covered range. This can happen for static constrained subtypes, as well as nonstatic or unconstrained subtypes. It cannot, however, happen if the case_statement has the discrete_choice others, because others covers all values, even those outside the subtype.

10.c/3 • {AI95-00114-01} {AI05-0188-1} If the compiler chooses to represent the value of an expression of an unconstrained subtype in a way that includes values outside the bounds of the subtype, then those values can be outside the covered range. For example, if X: Integer := Integer’Last, and the case selecting_expression is X+1, then the implementation might choose to produce the correct value, which is outside the bounds of Integer. (It might raise Constraint_Error instead.) This case can only happen for nongeneric subtypes that are either unconstrained or non-static (or both). It can only happen if there is no others discrete_choice.

10.d In the uninitialized variable case, the value might be anything; hence, any alternative can be chosen, or Constraint_Error can be raised. (We intend to prevent, however, jumping to random memory locations and the like.) In the out-of-range case, the behavior is more sensible: if there is an others, then the implementation may choose to raise Constraint_Error on the evaluation of the expression (as usual), or it may choose to correctly evaluate the expression and therefore choose the others alternative. Otherwise (no others), Constraint_Error is raised either way — on the expression evaluation, or for the case_statement itself.

For an enumeration type with a discontiguous set of internal codes (see 13.4), the only way to get values in between the proper values is via an object with an invalid representation; there is no “out-of-range” situation that can produce them.

10.e Dynamic Semantics

11/3 {AI05-0188-1} For the execution of a case_statement the selecting_expression is first evaluated.

12/3 {AI05-0188-1} If the value of the selecting_expression is covered by the discrete_choice_list of some case_statement_alternative, then the sequence_of_statements of the _alternative is executed.

13 Otherwise (the value is not covered by any discrete_choice_list, perhaps due to being outside the base range), Constraint_Error is raised.

13.a Ramification: In this case, the value is outside the base range of its type, or is an invalid representation.

NOTES

5 The execution of a case_statement chooses one and only one alternative. Qualification of the expression of a case_statement by a static subtype can often be used to limit the number of choices that need be given explicitly.
Examples of case statements:

```ada
case Sensor is
  when Elevation => Record_Elevation(Sensor_Value);
  when Azimuth => Record_Azimuth(Sensor_Value);
  when Distance => Record_Distance(Sensor_Value);
  when others => null;
end case;
```

```ada
case Today is
  when Mon => Compute_Initial_Balance;
  when Fri => Compute_Closing_Balance;
  when Tue .. Thu => Generate_Report(Today);
  when Sat .. Sun => null;
end case;
```

```ada
case Bin_Number(Count) is
  when 1 => Update_Bin(1);
  when 2 => Update_Bin(2);
  when 3 | 4 =>
    Empty_Bin(1);
    Empty_Bin(2);
  when others => raise Error;
end case;
```

Incompatibilities With Ada 83

In Ada 95, function calls and type conversions are names, whereas in Ada 83, they were expressions. Therefore, if the expression of a case_statement is a function_call or type_conversion, and the result subtype is static, it is illegal to specify a choice outside the bounds of the subtype. For this case in Ada 83 choices only are required to be in the base range of the type.

In addition, the rule about which choices must be covered is unchanged in Ada 95. Therefore, for a case_statement whose expression is a function_call or type_conversion, Ada 83 required covering all choices in the base range, while Ada 95 only requires covering choices in the bounds of the subtype. If the case_statement does not include an others discrete_choice, then a legal Ada 83 case_statement will be illegal in Ada 95 if the bounds of the subtype are different than the bounds of the base type.

Extensions to Ada 83

In Ada 83, the expression in a case_statement is not allowed to be of a generic formal type. This restriction is removed in Ada 95; an others discrete_choice is required instead.

In Ada 95, a function call is the name of an object; this was not true in Ada 83 (see 4.1, “Names”). This change makes the following case_statement legal:

```ada
subtype S is Integer range 1..2;
function F return S;
case F is
  when 1 => ...;
  when 2 => ...;
-- No others needed.
end case;
```

{AI05-0005-1} Note that the result subtype given in a function renaming_declaration is ignored; for a case_statement whose expression calls a such a function, the full coverage rules are checked using the result subtype of the original function. Note that predefined operators such as "+=" have an unconstrained result subtype (see 4.5.1). Note that generic formal functions do not have static result subtypes. Note that the result subtype of an inherited subprogram need not correspond to any nameable subtype; there is still a perfectly good result subtype, though.

Wording Changes from Ada 83

Ada 83 forgot to say what happens for “legally” out-of-bounds values.

We take advantage of rules and terms (e.g. cover a value) defined for discrete_choices and discrete_choice_lists in 3.8.1, “Variant Parts and Discrete Choices”.

In the Name Resolution Rule for the case expression, we no longer need RM83-5.4(3)’s “which must be determinable independently of the context in which the expression occurs, but using the fact that the expression must be of a discrete type,” because the expression is now a complete context. See 8.6, “The Context of Overload Resolution”.

13 December 2012
Since type_conversions are now defined as names, their coverage rule is now covered under the general rule for names, rather than being separated out along with qualified_expressions.

Wording Changes from Ada 2005

\{AI05-0003-1\} Rewording to reflect that a qualified_expression is now a name.
\{AI05-0153-3\} Revised for changes to discrete_choices made to allow static predicates (see 3.2.4) as case choices (see 3.8.1).
\{AI05-0188-1\} Added the selecting_prefix to make this wording consistent with case_expression, and to clarify which expression is being talked about in the wording.

5.5 Loop Statements

[A loop_statement includes a sequence_of_statements that is to be executed repeatedly, zero or more times.]

Syntax

```
loop_statement ::= [loop_statement_identifier:] [iteration_scheme] loop sequence_of_statements end loop [loop_identifier];
```

\{AI05-0139-2\} iteration_scheme ::= while condition | for loop_parameter_specification | for iterator_specification

```
loop_parameter_specification ::= defining_identifier in [reverse] discrete_subtype_definition
```

If a loop_statement has a loop_statement_identifier, then the identifier shall be repeated after the end loop; otherwise, there shall not be an identifier after the end loop.

Static Semantics

A loop_parameter_specification declares a loop parameter, which is an object whose subtype is that defined by the discrete_subtype_definition.

Dynamic Semantics

For the execution of a loop_statement, the sequence_of_statements is executed repeatedly, zero or more times, until the loop_statement is complete. The loop_statement is complete when a transfer of control occurs that transfers control out of the loop, or, in the case of an iteration_scheme, as specified below.

For the execution of a loop_statement with a while iteration_scheme, the condition is evaluated before each execution of the sequence_of_statements; if the value of the condition is True, the sequence_of_statements is executed; if False, the execution of the loop_statement is complete.

\{AI05-0139-2\} \{AI05-0262-1\} For the execution of a loop_statement with the for iteration_scheme being for loop_parameter_specification, the loop_parameter_specification is first elaborated. This elaboration creates the loop parameter and elaborates the discrete_subtype_definition. If the discrete_subtype_definition defines a subtype with a null range, the execution of the loop_statement is complete. Otherwise, the sequence_of_statements is executed once for each value of the discrete subtype defined by the discrete_subtype_definition that satisfies the predicate of the subtype (or until the loop is left as a consequence of a transfer of control). Prior to each such iteration, the corresponding value of the discrete
subtype is assigned to the loop parameter. These values are assigned in increasing order unless the reserved word reverse is present, in which case the values are assigned in decreasing order.

**Ramification:** The order of creating the loop parameter and evaluating the discrete_subtype_definition doesn't matter, since the creation of the loop parameter has no side effects (other than possibly raising Storage_Error, but anything can do that).

\{AI05-0262-1\} **Reason:** If there is a predicate, the loop still visits the values in the order of the underlying base type; the order of the values in the predicate is irrelevant. This is the case so that the following loops have the same sequence of calls and parameters on procedure Call for any subtype S:

```ada
for I in S loop
  Call (I);
end loop;
for I in S'Base loop
  if I in S then
    Call (I);
  end if;
end loop;
```

\{AI05-0262-1\} [For details about the execution of a loop_statement with the iteration_scheme being for iterator_specification, see 5.5.2.]

**NOTES**

6 A loop parameter is a constant; it cannot be updated within the sequence_of_statements of the loop (see 3.3).

7 An object_declaration should not be given for a loop parameter, since the loop parameter is automatically declared by the loop_parameter_specification. The scope of a loop parameter extends from the loop_parameter_specification to the end of the loop_statement, and the visibility rules are such that a loop parameter is only visible within the sequence_of_statements of the loop.

**Implementation Note:** An implementation could give a warning if a variable is hidden by a loop_parameter_specification.

8 The discrete_subtype_definition of a for loop is elaborated just once. Use of the reserved word reverse does not alter the discrete subtype defined, so that the following iteration_schemes are not equivalent; the first has a null range.

```ada
for J in reverse 1 .. 0
for J in 0 .. 1
```

**Ramification:** If a loop_parameter_specification has a static discrete range, the subtype of the loop parameter is static.

**Examples**

**Example of a loop statement without an iteration scheme:**

```ada
loop
  Get(Current_Character);
  exit when Current_Character = '*';
end loop;
```

**Example of a loop statement with a while iteration scheme:**

```ada
while Bid(N).Price < Cut_Off.Price loop
  Record_Bid(Bid(N).Price);
  N := N + 1;
end loop;
```

**Example of a loop statement with a for iteration scheme:**

```ada
for J in Buffer'Range loop  -- works even with a null range
  if Buffer(J) /= Space then
    Put(Buffer(J));
  end if;
end loop;
```
Example of a loop statement with a name:

```
Summation:
  while Next /= Head loop -- see 3.10.1
    Sum := Sum + Next.Value;
    Next := Next.Succ;
  end loop Summation;
```

Wording Changes from Ada 83

The constant-ness of loop parameters is specified in 3.3, “Objects and Named Numbers”.

Wording Changes from Ada 2005

Generalized iterator specifications are allowed in for loops; these are documented as an extension in the appropriate subclause.

5.5.1 User-Defined Iterator Types

Static Semantics

The following language-defined generic library package exists:

```
generic
  type Cursor;
  with function Has_Element (Position : Cursor) return Boolean;
package Ada.Iterator_Interfaces is
  pragma Pure (Iterator_Interfaces);
  type Forward_Iterator is limited interface;
    function First (Object : Forward_Iterator) return Cursor is abstract;
    function Next (Object : Forward_Iterator; Position : Cursor) return Cursor is abstract;
  type Reversible_Iterator is limited interface and Forward_Iterator;
    function Last (Object : Reversible_Iterator) return Cursor is abstract;
    function Previous (Object : Reversible_Iterator; Position : Cursor) return Cursor is abstract;
end Ada.Iterator_Interfaces;
```

An iterator type is a type descended from the Forward_Iterator interface from some instance of Ada.Iterator_Interfaces. A reversible iterator type is a type descended from the Reversible_Iterator interface from some instance of Ada.Iterator_Interfaces. An iterator object is an object of an iterator type. A reversible iterator object is an object of a reversible iterator type. The formal subtype Cursor from the associated instance of Ada.Iterator_Interfaces is the iteration cursor subtype for the iterator type.

The following type-related operational aspects may be specified for an indexable container type T (see 4.1.6):

Default Iterator

This aspect is specified by a name that denotes exactly one function declared immediately within the same declaration list in which T is declared, whose first parameter is of type T or T'Class or an access parameter whose designated type is type T or T'Class, whose other parameters, if any, have default expressions, and whose result type is an iterator type. This function is the default iterator function for T. Its result subtype is the default iterator subtype for T. The iteration cursor subtype for the default iterator subtype is the default cursor subtype for T.

Aspect Description for Default Iterator: Default iterator to be used in for loops.

Iterator Element

This aspect is specified by a name that denotes a subtype. This is the default element subtype for T.
**Aspect Description for Iterator Element:** Element type to be used for user-defined iterators.

These aspects are inherited by descendants of type \( T \) (including \( T \text{Class} \)).

\{AI05-0139-2\} \{AI05-0292-1\} An iterable container type is an indexable container type with specified Default Iterator and Iterator Element aspects. A reversible iterable container type is an iterable container type with the default iterator type being a reversible iterator type. An iterable container object is an object of an iterable container type. A reversible iterable container object is an object of a reversible iterable container type.

**Glossary entry:** An iterable container type is one that has user-defined behavior for iteration, via the Default Iterator and Iterator Element aspects.

**Legality Rules**

\{AI05-0139-2\} \{AI05-0292-1\} The Constant Indexing aspect (if any) of an iterable container type \( T \) shall denote exactly one function with the following properties:

- the result type of the function is covered by the default element type of \( T \) or is a reference type (see 4.1.5) with an access discriminant designating a type covered by the default element type of \( T \);
- the type of the second parameter of the function covers the default cursor type for \( T \);
- if there are more than two parameters, the additional parameters all have default expressions.

This function (if any) is the default constant indexing function for \( T \).

**Ramification:** This does not mean that Constant Indexing has to designate only one subprogram, only that there is only one routine that meets all of these properties. There can be other routines designated by Constant Indexing, but they cannot have the profile described above. For instance, map containers have a version of Constant Indexing that takes a key instead of a cursor; this is allowed.

\{AI05-0139-2\} \{AI05-0292-1\} The Variable Indexing aspect (if any) of an iterable container type \( T \) shall denote exactly one function with the following properties:

- the result type of the function is a reference type (see 4.1.5) with an access discriminant designating a type covered by the default element type of \( T \);
- the type of the second parameter of the function covers the default cursor type for \( T \);
- if there are more than two parameters, the additional parameters all have default expressions.

This function (if any) is the default variable indexing function for \( T \).

**Extensions to Ada 2005**

\{AI05-0139-2\} User-defined iterator types are new in Ada 2012.

### 5.5.2 Generalized Loop Iteration

\{AI05-0139-2\} Generalized forms of loop iteration are provided by an iterator specification.

**Syntax**

\{AI05-0139-2\} \{AI05-0292-1\}

```
iterator_specification ::= 
defining_identifier in [reverse] iterator_name 
| defining_identifier [; subtype_indication] of [reverse] iterable_name
```

**Name Resolution Rules**

\{AI05-0139-2\} \{AI05-0292-1\} For the first form of iterator specification, called a generalized iterator, the expected type for the iterator name is any iterator type. For the second form of iterator specification, the expected type for the iterable name is any array or iterable container type.
the iterable_name denotes an array object, the iterator_specification is called an array component iterator; otherwise it is called a container element iterator.

3.a.1/3

Glossary entry: An iterator is a construct that is used to loop over the elements of an array or container. Iterators may be user defined, and may perform arbitrary computations to access elements from a container.

Legality Rules

4/3

{AI05-0139-2} If the reserved word reverse appears, the iterator_specification is a reverse iterator; otherwise it is a forward iterator. In a reverse generalized iterator, the iterator_name shall be of a reversible iterator type. In a reverse container element iterator, the default iterator type for the type of the iterable_name shall be a reversible iterator type.

5/3

{AI05-0139-2} The type of the subtype_indication, if any, of an array component iterator shall cover the component type of the type of the iterable_name. The type of the subtype_indication, if any, of a container element iterator shall cover the default element type for the type of the iterable_name.

6/3

{AI05-0139-2} In a container element iterator whose iterable_name has type T, if the iterable_name denotes a constant or the Variable_Indexing aspect is not specified for T, then the Constant_Indexing aspect shall be specified for T.

Static Semantics

7/3

{AI05-0139-2} {AI05-0269-1} {AI05-0292-1} An iterator_specification declares a loop parameter. In a generalized iterator, the nominal subtype of the loop parameter is the iteration cursor subtype. In an array component iterator or a container element iterator, if a subtype_indication is present, it determines the nominal subtype of the loop parameter. In an array component iterator, if a subtype_indication is not present, the nominal subtype of the loop parameter is the component subtype of the type of the iterable_name. In a container element iterator, if a subtype_indication is not present, the nominal subtype of the loop parameter is the default element subtype for the type of the iterable_name.

8/3

{AI05-0139-2} {AI05-0292-1} In a generalized iterator, the loop parameter is a constant. In an array component iterator, the loop parameter is a constant if the iterable_name denotes a constant; otherwise it denotes a variable. In a container element iterator, the loop parameter is a constant if the iterable_name denotes a constant, or if the Variable_Indexing aspect is not specified for the type of the iterable_name; otherwise it is a variable.

Dynamic Semantics

9/3

{AI05-0139-2} For the execution of a loop_statement with an iterator_specification, the iterator_specification is first elaborated. This elaboration elaborates the subtype_indication, if any.

10/3

{AI05-0139-2} For a generalized iterator, the loop parameter is created, the iterator_name is evaluated, and the denoted iterator object becomes the loop iterator. In a forward generalized iterator, the operation First of the iterator type is called on the loop iterator, to produce the initial value for the loop parameter. If the result of calling Has_Element on the initial value is False, then the execution of the loop_statement is complete. Otherwise, the sequence of statements is executed and then the Next operation of the iterator type is called with the loop iterator and the current value of the loop parameter to produce the next value to be assigned to the loop parameter. This repeats until the result of calling Has_Element on the loop parameter is False, or the loop is left as a consequence of a transfer of control. For a reverse generalized iterator, the operations Last and Previous are called rather than First and Next.

11/3

{AI05-0139-2} {AI05-0292-1} For an array component iterator, the iterable_name is evaluated and the denoted array object becomes the array for the loop. If the array for the loop is a null array, then the execution of the loop_statement is complete. Otherwise, the sequence of statements is executed with the loop parameter denoting each component of the array for the loop, using a canonical order of
components, which is last dimension varying fastest (unless the array has convention Fortran, in which case it is first dimension varying fastest). For a forward array component iterator, the iteration starts with the component whose index values are each the first in their index range, and continues in the canonical order. For a reverse array component iterator, the iteration starts with the component whose index values are each the last in their index range, and continues in the reverse of the canonical order. The loop iteration proceeds until the sequence of statements has been executed for each component of the array for the loop, or until the loop is left as a consequence of a transfer of control.

\{AI05-0139-2\} \{AI05-0292-1\} For a container element iterator, the iterable name is evaluated and the denoted iterable container object becomes the iterable container object for the loop. The default iterator function for the type of the iterable container object for the loop is called on the iterable container object and the result is the loop iterator. An object of the default cursor subtype is created (the loop cursor).

\{AI05-0139-2\} \{AI05-0292-1\} For a forward container element iterator, the operation First of the iterator type is called on the loop iterator, to produce the initial value for the loop cursor. If the result of calling Has Element on the initial value is False, then the execution of the loop statement is complete. Otherwise, the sequence of statements is executed with the loop parameter denoting an indexing (see 4.1.6) into the iterable container object for the loop, with the only parameter to the indexing being the current value of the loop cursor; then the Next operation of the iterator type is called with the loop iterator and the loop cursor to produce the next value to be assigned to the loop cursor. This repeats until the result of calling Has Element on the loop cursor is False, or until the loop is left as a consequence of a transfer of control. For a reverse container element iterator, the operations Last and Previous are called rather than First and Next. If the loop parameter is a constant (see above), then the indexing uses the default constant indexing function for the type of the iterable container object for the loop; otherwise it uses the default variable indexing function.

Examples

\{AI05-0269-1\} -- Array component iterator example:
for Element of Board loop -- See 3.6.1.
   Element := Element * 2.0; -- Double each element of Board, a two-dimensional array.
end loop;

\{AI05-0268-1\} For examples of use of generalized iterators, see A.18.32 and the corresponding container packages in A.18.2 and A.18.3.

Extensions to Ada 2005

\{AI05-0139-2\} Generalized forms of loop iteration are new.

5.6 Block Statements

[A block statement encloses a handled_sequence_of_statements optionally preceded by a declarative_part.]

Syntax

```
block_statement ::= 
   [block_statement_identifier:]
   [declare 
      declarative_part]
   begin 
      handled_sequence_of_statements 
   end [block_identifier];
```
If a block_statement has a block_statement_identifier, then the identifier shall be repeated after the end; otherwise, there shall not be an identifier after the end.

Static Semantics

A block_statement that has no explicit declarative_part has an implicit empty declarative_part.

Ramification: Thus, other rules can always refer to the declarative_part of a block_statement.

Dynamic Semantics

The execution of a block_statement consists of the elaboration of its declarative_part followed by the execution of its handled_sequence_of_statements.

Examples

Example of a block statement with a local variable:

Swap:

```ada
declare
    Temp : Integer;
begin
    Temp := V; V := U; U := Temp;
end Swap;
```

Ramification: If task objects are declared within a block_statement whose execution is completed, the block_statement is not left until all its dependent tasks are terminated (see 7.6). This rule applies to completion caused by a transfer of control.

Within a block_statement, the block name can be used in expanded names denoting local entities such as Swap.Temp in the above example (see 4.1.3).

Wording Changes from Ada 83

The syntax rule for block_statement now uses the syntactic category handled_sequence_of_statements.

5.7 Exit Statements

[An exit_statement is used to complete the execution of an enclosing loop_statement; the completion is conditional if the exit_statement includes a condition.]

Syntax

```ada
exit_statement ::= exit [loop_name] [when condition];
```

Name Resolution Rules

The loop_name, if any, in an exit_statement shall resolve to denote a loop_statement.

Legality Rules

Each exit_statement applies to a loop_statement; this is the loop_statement being exited. An exit_statement with a name is only allowed within the loop_statement denoted by the name, and applies to that loop_statement. An exit_statement without a name is only allowed within a loop_statement, and applies to the innermost enclosing one. An exit_statement that applies to a given loop_statement shall not appear within a body or accept_statement, if this construct is itself enclosed by the given loop_statement.
Dynamic Semantics

For the execution of an exit_statement, the condition, if present, is first evaluated. If the value of the condition is True, or if there is no condition, a transfer of control is done to complete the loop_statement. If the value of the condition is False, no transfer of control takes place.

NOTES
9 Several nested loops can be exited by an exit_statement that names the outer loop.

Examples

Examples of loops with exit statements:

```ada
for N in 1 .. Max_Num_Items loop
  Get_New_Item(New_Item);
  Merge_Item(New_Item, Storage_File);
  exit when New_Item = Terminal_Item;
end loop;

Main_Cycle:
  loop
    -- initial statements
    exit Main_Cycle when Found;
    -- final statements
  end loop Main_Cycle;
```

5.8 Goto Statements

[A goto_statement specifies an explicit transfer of control from this statement to a target statement with a given label.]

Syntax

```
goto_statement ::= goto label_name;
```

Name Resolution Rules

The label_name shall resolve to denote a label; the statement with that label is the target statement.

Legality Rules

The innermost sequence_of_statements that encloses the target statement shall also enclose the goto_statement. Furthermore, if a goto_statement is enclosed by an accept_statement or a body, then the target statement shall not be outside this enclosing construct.

Ramification: The goto_statement can be a statement of an inner sequence._

It follows from the second rule that if the target statement is enclosed by such a construct, then the goto_statement cannot be outside.

Dynamic Semantics

The execution of a goto_statement transfers control to the target statement, completing the execution of any compound_statement that encloses the goto_statement but does not enclose the target.

NOTES
10 The above rules allow transfer of control to a statement of an enclosing sequence_of_statements but not the reverse. Similarly, they prohibit transfers of control such as between alternatives of a case_statement, if_statement, or select_statement; between exception_handlers; or from an exception_handler of a handled_sequence_of_statements back to its sequence_of_statements.
Examples

Example of a loop containing a goto statement:

<<Sort>>
for I in 1 .. N-1 loop
  if A(I) > A(I+1) then
    Exchange(A(I), A(I+1));
    goto Sort;
  end if;
end loop;
6 Subprograms

A subprogram is a program unit or intrinsic operation whose execution is invoked by a subprogram call. There are two forms of subprogram: procedures and functions. A procedure call is a statement; a function call is an expression and returns a value. The definition of a subprogram can be given in two parts: a subprogram declaration defining its interface, and a subprogram_body defining its execution. [Operators and enumeration literals are functions.]

To be honest: A function call is an expression, but more specifically it is a name.

Glossary entry: A subprogram is a section of a program that can be executed in various contexts. It is invoked by a subprogram call that may qualify the effect of the subprogram through the passing of parameters. There are two forms of subprograms: functions, which return values, and procedures, which do not.

Glossary entry: A function is a form of subprogram that returns a result and can be called as part of an expression.

Glossary entry: A procedure is a form of subprogram that does not return a result and can only be called by a statement.

{AI05-0299-1} A callable entity is a subprogram or entry (see Section 9.5.2). A callable entity is invoked by a call; that is, a subprogram call or entry call. A callable construct is a construct that defines the action of a call upon a callable entity: a subprogram_body, entry_body, or accept_statement.

Ramification: Note that “callable entity” includes predefined operators, enumeration literals, and abstract subprograms. “Call” includes calls of these things. They do not have callable constructs, since they don’t have completions.

6.1 Subprogram Declarations

[A subprogram_declaration declares a procedure or function.]

Syntax

{AI95-00218-03} {AI05-0183-1} subprogram_declaration ::= {0/1} {AI95-00348-01} abstract_subprogram_declaration ::= {0/1} subprogram_specification {0/1} is abstract;

{AI95-00348-01} subprogram_specification ::= {0/1} procedure_specification {0/1} function_specification

procedure_specification ::= {AI95-00348-01} procedure defining_program_unit_name parameter_profile

function_specification ::= {AI95-00348-01} function defining_designator parameter_and_result_profile

designator ::= {parent_unit_name . }identifier | operator_symbol

defining_designator ::= defining_program_unit_name | defining_operator_symbol

defining_program_unit_name ::= {parent_unit_name . }defining_identifier

[The optional parent_unit_name is only allowed for library units (see 10.1.1).]

operator_symbol ::= string_literal
The sequence of characters in an operator_symbol shall form a reserved word, a delimiter, or compound delimiter that corresponds to an operator belonging to one of the six categories of operators defined in subclause 4.5 (spaces are not allowed and the case of letters is not significant).

Reason: The “sequence of characters” of the string literal of the operator is a technical term (see 2.6), and does not include the surrounding quote characters. As defined in 2.2, lexical elements are “formed” from a sequence of characters. Spaces are not allowed, and upper and lower case is not significant. See 2.2 and 2.9 for rules related to the use of other format characters in delimiters and reserved words.

Name Resolution Rules

A formal parameter is an object that represents the actual parameter passed to the subprogram in a call; it is declared by a parameter_specification. For a formal parameter, the expected type for its default_expression, if any, is that of the formal parameter.

Legality Rules

The parameter mode of a formal parameter conveys the direction of information transfer with the actual parameter: in, in out, or out. Mode in is the default, and is the mode of a parameter defined by an access_definition. The formal parameters of a function, if any, shall have the mode in.

A default_expression is only allowed in a parameter_specification for a formal parameter of mode in.

A subprogram_declaration or a generic_subprogram_declaration requires a completion; unless the Import aspect (see B.1) is True for the declaration, the completion shall be a body or, a renaming_declaration (see 8.5), or a pragma Import (see B.1). [A completion is not allowed for an abstract_subprogram_declaration (see 3.9.3), or a null_procedure_declaration (see 6.7), or an expression_function_declaration (see 6.8).]

Ramification: Abstract subprograms and null procedures, and expression functions are not declared by subprogram_declarations, and so do not require completion (although the latter two can be completions). Protected subprograms are declared by subprogram_declarations, and so require completion. Note that an abstract subprogram is a subprogram, a null procedure is a subprogram, an expression function is a subprogram, and a protected subprogram is a subprogram, but a generic subprogram is not a subprogram.

When the Import aspect is True for any entity, no completion is allowed (see B.1).
Ramification: By contrast, generic_formal_parameter_declarations are visible to subsequent declarations in the same
generic_formal_part.

Static Semantics

The profile of (a view of) a callable entity is either a parameter_profile or
parameter_and_result_profile; it embodies information about the interface to that entity — for example,
the profile includes information about parameters passed to the callable entity. All callable entities have a
profile — enumeration literals, other subprograms, and entries. An access-to-subprogram type has a
designated profile. Associated with a profile is a calling convention. A subprogram_declaration
declares a procedure or a function, as indicated by the initial reserved word, with name and profile as
given by its specification.

{AI95-00231-01} {AI95-00318-02} The nominal subtype of a formal parameter is the subtype
determined by the optional null_exclusion and the subtype_mark, or defined by the
access_definition, in the parameter_specification. The nominal subtype of a function result is the
subtype determined by the optional null_exclusion and the subtype_mark, or defined by the
access_definition, in the parameter and result_profile.

{AI05-0142-4} An explicitly aliased parameter is a formal parameter whose parameter_specification
includes the reserved word aliased.

{AI95-00231-01} {AI95-00254-01} {AI95-00318-02} An access parameter is a formal in parameter
specified by an access_definition. An access result type is a function result type specified by an
access_definition. An access parameter or result type is of an anonymous access_general access_to_variable
type (see 3.10). [Access parameters of an access-to-object type allow dispatching calls to be
controlled by access values. Access parameters of an access-to-subprogram type permit calls to
subprograms passed as parameters irrespective of their accessibility level.]

Discussion: {AI95-00318-02} Access result types have normal accessibility and thus don't have any special properties
worth noting here.

The subtypes of a profile are:

- For any non-access parameters, the nominal subtype of the parameter.

- For any access parameters of an access-to-object type, the designated subtype
  of the parameter type.

- For any access parameters of an access-to-subprogram type, the
  subtypes of the designated profile of the parameter type.

- For any non-access result, the nominal subtype of the
  function result. For any result, the result subtype.

- For any access result type of an access-to-object type, the designated subtype
  of the result type.

- For any access result type of an access-to-subprogram type, the
  subtypes of the designated profile of the result type.

[ The types of a profile are the types of those subtypes.]

{AI95-00348-01} {AI95-0177-1} [A subprogram declared by an abstract_subprogram_declaration is
abstract; a subprogram declared by a subprogram_declaration is not. See 3.9.3, “Abstract Types and
Subprograms”. Similarly, a procedure declared defined by a null procedure_declaration is a null
procedure; a procedure declared by a subprogram_declaration is not. See 6.7, “Null Procedures”.
Finally, a function declared by an expression_function_declaration is an expression function; a function
declared by a subprogram_declaration is not. See 6.8, “Expression Functions”.]
Dynamic Semantics

The elaboration of a `subprogram_declaration` or an `abstract_subprogram_declaration` has no effect.

NOTES

1. A `parameter_specification` with several identifiers is equivalent to a sequence of single `parameter_specifications`, as explained in 3.3.
2. Abstract subprograms do not have bodies, and cannot be used in a nondispatching call (see 3.9.3, “Abstract Types and Subprograms”).
3. The evaluation of `default_expression`s is caused by certain calls, as described in 6.4.1. They are not evaluated during the elaboration of the subprogram declaration.
4. Subprograms can be called recursively and can be called concurrently from multiple tasks.

Examples of subprogram declarations:

```ada
procedure Traverse_Tree;
procedure Increment(X : in out Integer);
procedure Right_Indent(Margin : out Line_Size); -- see 3.5.4
procedure Switch(From, To : in out Link); -- see 3.10.1
function Random return Probability; -- see 3.10.7
function Min_Cell(X : Link) return Cell; -- see 3.10.1
function Next_Frame(K : Positive) return Frame; -- see 3.10
function Dot_Product(Left, Right : Vector) return Real; -- see 3.6
function "*"(Left, Right : Matrix) return Matrix; -- see 3.6
```

Examples of `in` parameters with `default expressions`:

```ada
procedure Print_Header(Pages  : in Natural;
  Header : in Line := (1 .. Line'Last => ' '); -- see 3.6
  Center : in Boolean := True);
```

Extensions to Ada 83

The syntax for `abstract_subprogram_declaration` is added. The syntax for `parameter_specification` is revised to allow for access parameters (see 3.10).

Wording Changes from Ada 83

We have incorporated the rules from RM83-6.5, “Function Subprograms” here and in 6.3, “Subprogram Bodies”.

We have incorporated the definitions of RM83-6.6, “Parameter and Result Type Profile - Overloading of Subprograms” here.

The syntax rule for `defining_operator_symbol` is new. It is used for the defining occurrence of an `operator_symbol`, analogously to `defining_identifier`. Usage occurrences use the `direct_name` or `selector_name` syntactic categories. The syntax rules for `defining_designator` and `defining_program_unit_name` are new.

Extensions to Ada 95

Subprograms now allow `overriding_indicators` for better error checking of overriding.

An optional `null_exclusion` can be used in a formal parameter declaration. Similarly, an optional `null_exclusion` can be used in a function result.

The return type of a function can be an anonymous access type.
Wording Changes from Ada 95

{AI95-00254-01} A description of the purpose of anonymous access-to-subprogram parameters and the definition of the profile of subprograms containing them was added.

{AI95-00348-01} Split the production for subprogram specification in order to make the declaration of null procedures (see 6.7) easier.

{AI95-00348-01} Moved the Syntax and Dynamic Semantics for abstract subprogram declaration to 3.9.3, so that the syntax and semantics are together. This also keeps abstract and null subprograms similar.

{AI95-00395-01} Revised to allow other format characters in operator symbols in the same way as the underlying constructs.

Extensions to Ada 2005

{AI05-0142-4} Parameters can now be explicitly aliased, allowing parts of function results to designate parameters and forcing by-reference parameter passing.

{AI05-0143-1} The parameters of a function can now have any mode.

{AI05-0183-1} An optional aspect specification can be used in a subprogram declaration. This is described in 13.1.1.

{AI05-0177-1} Added expression functions (see 6.8) to the wording.

6.1.1 Preconditions and Postconditions

{AI05-0145-2} {AI05-0247-1} For a subprogram or entry, the following language-defined aspects may be specified with an aspect specification (see 13.1.1):

Pre

This aspect specifies a specific precondition for a callable entity; it shall be specified by an expression, called a specific precondition expression. If not specified for an entity, the specific precondition expression for the entity is the enumeration literal True.

To be honest: In this and the following rules, we are talking about the enumeration literal True declared in package Standard (see A.1), and not some other value or identifier True. That matters as some rules depend on full conformance of these expressions, which depends on the specific declarations involved.

Aspect Description for Pre: Precondition; a condition that must hold true before a call.

Pre'Class

This aspect specifies a class-wide precondition for an operation of a tagged type and its descendants; it shall be specified by an expression, called a class-wide precondition expression. If not specified for an entity, then if no other class-wide precondition applies to the entity, the class-wide precondition expression for the entity is the enumeration literal True.

Ramification: If other class-wide preconditions apply to the entity and no class-wide precondition is specified, no class-wide precondition is defined for the entity; of course, the class-wide preconditions (of ancestors) that are still going to be checked. We need subprograms that don't have ancestors and don't specify a class-wide precondition to have a class-wide precondition of True, so that adding such a precondition to a descendant has no effect (necessary as a dispatching call through the root routine would not check any precondition).

Aspect Description for Pre'Class: Precondition inherited on type derivation.

Post

This aspect specifies a specific postcondition for a callable entity; it shall be specified by an expression, called a specific postcondition expression. If not specified for an entity, the specific postcondition expression for the entity is the enumeration literal True.

Aspect Description for Post: Postcondition; a condition that must hold true after a call.
AI05-0262-1 Post'Class
This aspect specifies a class-wide postcondition for an operation of a tagged type and its
descendants; it shall be specified by an expression, called a class-wide postcondition
expression. If not specified for an entity, the class-wide postcondition expression for the
entity is the enumeration literal True.

Aspect Description for Post'Class: Postcondition inherited on type derivation.

Name Resolution Rules

AI05-0145-2 The expected type for a precondition or postcondition expression is any boolean type.

AI05-0145-2 Within the expression for a Pre'Class or Post'Class aspect for a primitive
subprogram of a tagged type T, a name that denotes a formal parameter of type T is interpreted as having
type T'Class. Similarly, a name that denotes a formal access parameter of type access-to-T is interpreted
as having type access-to-T'Class. [This ensures that the expression is well-defined for a primitive
subprogram of a type descended from T.]

AI05-0145-2 For an attribute_reference with attribute_designator Old, if the attribute
reference has an expected type or shall resolve to a given type, the same applies to the
prefix; otherwise, the prefix shall be resolved independently of context.

Legality Rules

AI05-0145-2 {AI05-0230-1} The Pre or Post aspect shall not be specified for an abstract subprogram or
a null procedure. [Only the Pre'Class and Post'Class aspects may be specified for such a subprogram.]

Discussion: {AI05-0183-1} Pre'Class and Post'Class can only be specified on primitive routines of tagged types, by a
blanket rule found in 13.1.1.

AI05-0247-1 {AI05-0254-1} If a type T has an implicitly declared subprogram P inherited from a
parent type T1 and a homograph (see 8.3) of P from a progenitor type T2, and

• the corresponding primitive subprogram P1 of type T1 is neither null nor abstract; and
• the class-wide precondition expression True does not apply to P1 (implicitly or explicitly); and
• there is a class-wide precondition expression that applies to the corresponding primitive
subprogram P2 of T2 that does not fully conform to any class-wide precondition expression that
applies to P1,

then:

• If the type T is abstract, the implicitly declared subprogram P is abstract.

• Otherwise, the subprogram P requires overriding and shall be overridden with a nonabstract
subprogram.

Discussion: We use the term "requires overriding" here so that this rule is taken into account when calculating
visibility in 8.3; otherwise we would have a mess when this routine is overridden.

Reason: Such an inherited subprogram would necessarily violate the Liskov Substitutability Principle (LSP) if called
via a dispatching call from an ancestor other than the one that provides the called body. In such a case, the class-wide
precondition of the actual body is stronger than the class-wide precondition of the ancestor. If we did not enforce that
precondition for the body, the body could be called when the precondition it knows about is False — such
"counterfeiting" of preconditions has to be avoided. But enforcing the precondition violates LSP. We do not want the
language to be implicitly creating bodies that violate LSP; the programmer can still write an explicit body that calls the
appropriate parent subprogram. In that case, the violation of LSP is explicitly in the code and obvious to code
reviewers (both human and automated).

We have to say that the subprogram is abstract for an abstract type in this case, so that the next concrete type has to
override it for the reasons above. Otherwise, inserting an extra level of abstract types would eliminate the requirement
to override (as there is only one declared operation for the concrete type), and that would be bad for the reasons given
above.
Ramification: This requires the set of class-wide preconditions that apply to the interface routine to be strictly stronger than those that apply to the concrete routine. Since full conformance requires each name to denote the same declaration, it is unlikely that independently declared preconditions would conform. This rule does allow “diamond inheritance” of preconditions, and of course no preconditions at all match.

We considered adopting a rule that would allow examples where the expressions would conform after all inheritance has been applied, but this is complex and is not likely to be common in practice. Since the penalty here is just that an explicit overriding is required, the complexity is too much.

\{AI05-0247-1\} If a renaming of a subprogram or entry \$1\ overrides an inherited subprogram \$2\, then the overriding is illegal unless each class-wide precondition expression that applies to \$1\ fully conforms to some class-wide precondition expression that applies to \$2\ and each class-wide precondition expression that applies to \$2\ fully conforms to some class-wide precondition expression that applies to \$1\.

Reason: Such an overriding subprogram would violate LSP, as the precondition of \$1\ would usually be different (and thus stronger) than the one known to a dispatching call through an ancestor routine of \$2\. This is always OK if the preconditions match, so we always allow that.

Ramification: This only applies to primitives of tagged types; other routines cannot have class-wide preconditions.

\{AI05-0145-2\} If a Pre'Class or Post'Class aspect is specified for a primitive subprogram of a tagged type \$T\, then the associated expression also applies to the corresponding primitive subprogram of each descendant of \$T\.

\{AI05-0145-2\} \{AI05-0262-1\} \{AI05-0290-1\} If performing checks is required by the Pre, Pre'Class, Post, or Post'Class assertion policies (see 11.4.2) in effect at the point of a corresponding aspect specification applicable to a given subprogram or entry, then the respective precondition or postcondition expressions are considered enabled.

Ramification: \{AI05-0290-1\} If a class-wide precondition or postcondition expression is enabled, it remains enabled when inherited by an overriding subprogram, even if the policy in effect is Ignore for the inheriting subprogram.

\{AI05-0273-1\} An expression is potentially unevaluated if it occurs within:

- any part of an if_expression other than the first condition;
- a dependent_expression of a case_expression;
- the right operand of a short-circuit control form; or
- a membership_choice other than the first of a membership operation.

\{AI05-0145-2\} For a prefix \$X\ that denotes an object of a nonlimited type, the following attribute is defined: \$X’Old\.

\{AI05-0145-2\} \{AI05-0262-1\} \{AI05-0273-1\} For each \$X’Old\ in a postcondition expression that is enabled, a constant is implicitly declared at the beginning of the subprogram or entry. The constant is of the type of \$X\ and is initialized to the result of evaluating \$X\ (as an expression) at the point of the constant declaration. The value of \$X’Old\ in the postcondition expression is the value of this constant; the type of \$X’Old\ is the type of \$X\. These implicit constant declarations occur in an arbitrary order.

\{AI05-0145-2\} \{AI05-0262-1\} \{AI05-0273-1\} Reference to this attribute is only allowed within a postcondition expression. The prefix of an Old attribute_reference shall not contain a Result_attribute_reference, nor an Old_attribute_reference, nor a use of an entity declared within the postcondition expression but not within prefix itself (for example, the loop parameter of an enclosing quantified_expression). The prefix of an Old_attribute_reference that is potentially unevaluated shall statically denote an entity.

Discussion: The prefix \$X\ can be any nonlimited object that obeys the syntax for prefix other than the few exceptions given above (discussed below). Useful cases are: the name of a formal parameter of mode [in] out, the name of a
global variable updated by the subprogram, a function call passing those as parameters, a subcomponent of those things, etc.

A qualified expression can be used to make an arbitrary expression into a valid prefix, so T'(X + Y)'Old is legal, even though (X + Y)'Old is not. The value being saved here is the sum of X and Y (a function result is an object). Of course, in this case "T"(X, Y)'Old is also legal, but the qualified expression is arguably more readable.

Note that F(X)'Old and F(X)'Old are not necessarily equal. The former calls F(X) and saves that value for later use during the postcondition. The latter saves the value of X, and during the postcondition, passes that saved value to F. In most cases, the former is what one wants (but it is not always legal, see below).

If X has controlled parts, adjustment and finalization are implied by the implicit constant declaration.

If postconditions are disabled, we want the compiler to avoid any overhead associated with saving 'Old values.

'Old makes no sense for limited types, because its implementation involves copying. It might make semantic sense to allow build-in-place, but it's not worth the trouble.

Reason: [AI05-0273-1] Since the prefix is evaluated unconditionally when the subprogram is called, we cannot allow it to include values that do not exist at that time (like 'Result and loop parameters of qualified expressions). We also do not allow it to include 'Old references, as those would be redundant (the entire prefix is evaluated when the subprogram is called), and allowing them would require some sort of order to the implicit constant declarations (because in A(Old)Old, we surely would want the value of Old evaluated before the A(Old) is evaluated).

{AI05-0273-1} In addition, we only allow simple names as the prefix of the Old attribute if the attribute reference might not be evaluated when the postcondition expression is evaluated. This is necessary because the Old prefixes have to be unconditionally evaluated when the subprogram is called; the compiler cannot in general know whether they will be needed in the postcondition expression. To see the problem, consider:

```
Table : array (1..10) of Integer := ...  
procedure Bar (I : in out Natural)  
    with Post => I > 0 and then Table(I)'Old = 1; -- Illegal
```

In this example, the compiler cannot know the value of I when the subprogram returns (since the subprogram execution can change it), and thus it does not know whether Table(I)'Old will be needed then. Thus it has to always create an implicit constant and evaluate Table(I) when Bar is called (because not having the value when it is needed is not acceptable). But if I = 0 when the subprogram is called, that evaluation will raise Constraint Error, and that will happen even if I is unchanged by the subprogram and the value of Table(I)'Old is not ultimately needed. It's easy to see how a similar problem could occur for a dereference of an access type. This would be mystifying (since the point of the short circuit is to eliminate this possibility, but it cannot do so). Therefore, we require the prefix of any Old attribute in such a context to statically denote an object, which eliminates anything that could change at during execution.

It is easy to work around most errors that occur because of this rule. Just move the 'Old to the outer object, before any indexing, dereferences, or components. (That does not work for function calls, however, nor does it work for array indexing if the index can change during the execution of the subprogram.)

{AI05-0145-2} For a prefix F that denotes a function declaration, the following attribute is defined:

F'Result

{AI05-0145-2} {AI05-0262-1} Within a postcondition expression for function F, denotes the result object of the function. The type of this attribute is that of the function result except within a Post'Class postcondition expression for a function with a controlling result or with a controlling access result. For a controlling result, the type of the attribute is T'Class, where T is the function result type. For a controlling access result, the type of the attribute is an anonymous access type whose designated type is T'Class, where T is the designated type of the function result type.

{AI05-0262-1} Use of this attribute is allowed only within a postcondition expression for F.

Dynamic Semantics

{AI05-0145-2} {AI05-0247-1} {AI05-0290-1} Upon a call of the subprogram or entry, after evaluating any actual parameters, precondition checks are performed as follows:

- The specific precondition check begins with the evaluation of the specific precondition expression that applies to the subprogram or entry, if it is enabled; if the expression evaluates to False, Assertions.Assertion_Error is raised; if the expression is not enabled, the check succeeds.
13 December 2012 Precondition and Postconditions

6.1.1

The class-wide precondition check begins with the evaluation of any enabled class-wide precondition expressions that apply to the subprogram or entry. If and only if all the class-wide precondition expressions evaluate to False, Assertions.Assertion_Error is raised.

**Ramification:** The class-wide precondition expressions of the entity itself as well as those of any parent or progenitor operations are evaluated, as these expressions apply to the corresponding operations of all descendants.

Class-wide precondition checks are performed for all appropriate calls, but only enabled precondition expressions are evaluated. Thus, the check would be trivial if no precondition expressions are enabled.

The precondition checks are performed in an arbitrary order, and if any of the class-wide precondition expressions evaluate to True, it is not specified whether the other class-wide precondition expressions are evaluated. The precondition checks and any check for elaboration of the subprogram body are performed in an arbitrary order. It is not specified whether in a call on a protected operation, the checks are performed before or after starting the protected action. For an entry call, the checks are performed prior to checking whether the entry is open.

**Reason:** We need to explicitly allow short-circuiting of the evaluation of the class-wide precondition check if any expression fails, as it consists of multiple expressions; we don't need a similar permission for the specific precondition check as it consists only of a single expression. Nothing is evaluated for the call after a check fails, as the failed check propagates an exception.

Upon successful return from a call of the subprogram or entry, prior to copying back any by-copy in out or out parameters, the postcondition check is performed. This consists of the evaluation of any enabled specific and class-wide postcondition expressions that apply to the subprogram or entry. If any of the postcondition expressions evaluate to False, then Assertions.Assertion_Error is raised. The postcondition expressions are evaluated in an arbitrary order, and if any postcondition expression evaluates to False, it is not specified whether any other postcondition expressions are evaluated. The postcondition check, and any constraint or predicate checks associated with in out or out parameters are performed in an arbitrary order.

**Ramification:** The class-wide postcondition expressions of the entity itself as well as those of any parent or progenitor operations are evaluated, as these apply to all descendants; in contrast, only the specific postcondition of the entity applies. Postconditions can always be evaluated inside the invoked body.

If a precondition or postcondition check fails, the exception is raised at the point of the call[; the exception cannot be handled inside the called subprogram or entry]. Similarly, any exception raised by the evaluation of a precondition or postcondition expression is raised at the point of call.

For any subprogram or entry call (including dispatching calls), the checks that are performed to verify specific precondition expressions and specific and class-wide postcondition expressions are determined by those for the subprogram or entry actually invoked. Note that the class-wide postcondition expressions verified by the postcondition check that is part of a call on a primitive subprogram of type T includes all class-wide postcondition expressions originating in any progenitor of T, even if the primitive subprogram called is inherited from a type T1 and some of the postcondition expressions do not apply to the corresponding primitive subprogram of T1.

**Ramification:** This applies to access-to-subprogram calls, dispatching calls, and to statically bound calls. We need this rule to cover statically bound calls as well, as specific pre- and postconditions are not inherited, but the subprogram might be.

For concrete subprograms, we require the original specific postcondition to be evaluated as well as the inherited class-wide postconditions in order that the semantics of an explicitly defined wrapper that does nothing but call the original subprogram is the same as that of an inherited subprogram.

Note that this rule does not apply to class-wide preconditions; they have their own rules mentioned below.
The class-wide precondition check for a call to a subprogram or entry consists solely of checking the class-wide precondition expressions that apply to the denoted callable entity (not necessarily the one that is invoked).

**Ramification:** For a dispatching call, we are talking about the Pre'Class(es) that apply to the subprogram that the dispatching call is resolving to, not the Pre'Class(es) for the subprogram that is ultimately dispatched to. The class-wide precondition of the resolved call is necessarily the same or stronger than that of the invoked call. For a statically bound call, these are the same; for an access-to-subprogram, (which has no class-wide preconditions of its own), we check the class-wide preconditions of the invoked routine.

**Implementation Note:** These rules imply that logically, class-wide preconditions of routines must be checked at the point of call (other than for access-to-subprogram calls, which must be checked in the body, probably using a wrapper). Specific preconditions that might be called with a dispatching call or via an access-to-subprogram value must be checked inside of the subprogram body. In contrast, the postcondition checks always need to be checked inside the body of the routine. Of course, an implementation can evaluate all of these at the point of call for statically bound calls if the implementation uses wrappers for dispatching bodies and for Access values.

There is no requirement for an implementation to generate special code for routines that are imported from outside of the Ada program. That's because there is a requirement on the programmer that the use of interfacing aspects do not violate Ada semantics (see B.1). That includes making pre- and postcondition checks. For instance, if the implementation expects routines to make their own postcondition checks in the body before returning, C code can be assumed to do this (even though that is highly unlikely). That's even though the formal definition of those checks is that they are evaluated at the call site. Note that pre- and postconditions can be very useful for verification tools (even if they aren't checked), because they tell the tool about the expectations on the foreign code that it most likely cannot analyze.

For a call via an access-to-subprogram value, all precondition and postcondition checks performed are determined by the subprogram or entry denoted by the prefix of the Access attribute reference that produced the value.

**NOTES**

1. A precondition is checked just before the call. If another task can change any value that the precondition expression depends on, the precondition need not hold within the subprogram or entry body.

**Extensions to Ada 2005**

6.2 Formal Parameter Modes

[A parameter_specification declares a formal parameter of mode in, in out, or out.]

**Static Semantics**

A parameter is passed either by copy or by reference. [When a parameter is passed by copy, the formal parameter denotes a separate object from the actual parameter, and any information transfer between the two occurs only before and after executing the subprogram. When a parameter is passed by reference, the formal parameter denotes (a view of) the object denoted by the actual parameter; reads and updates of the formal parameter directly reference the actual parameter object.]

A type is a by-copy type if it is an elementary type, or if it is a descendant of a private type whose full type is a by-copy type. A parameter of a by-copy type is passed by copy, unless the formal parameter is explicitly aliased.

A type is a by-reference type if it is a descendant of one of the following:

- a tagged type;
- a task or protected type;
- an explicitly limited record type a nonprivate type with the reserved word limited in its declaration;
A limited private type is by reference only if it falls under one of the other categories.

- a composite type with a subcomponent of a by-reference type;
- a private type whose full type is a by-reference type.

A parameter of a by-reference type is passed by reference, as is an explicitly aliased parameter of any type. Each value of a by-reference type has an associated object. For a parenthesized expression, qualified_expression, or type_conversion, this object is the one associated with the operand. For a conditional_expression, this object is the one associated with the evaluated dependent_expression.

**Ramification:** By-reference parameter passing makes sense only if there is an object to reference; hence, we define such an object for each case.

Since tagged types are by-reference types, this implies that every value of a tagged type has an associated object. This simplifies things, because we can define the tag to be a property of the object, and not of the value of the object, which makes it clearer that object tags never change.

We considered simplifying things even more by making every value (and therefore every expression) have an associated object. After all, there is little semantic difference between a constant object and a value. However, this would cause problems for untagged types. In particular, we would have to do a constraint check on every read of a type conversion (or a renaming thereof) in certain cases.

We do not want this definition to depend on the view of the type; privateness is essentially ignored for this definition. Otherwise, things would be confusing (does the rule apply at the call site, at the site of the declaration of the subprogram, at the site of the return statement?), and requiring different calls to use different mechanisms would be an implementation burden.

C.6, “Shared Variable Control” says that a composite type with an atomic or volatile subcomponent is a by-reference type, among other things.

Every value of a limited by-reference type is the value of one and only one limited object. The associated object of a value of a limited by-reference type is the object whose value it represents. Two values of a limited by-reference type are the same if and only if they represent the value of the same object.

We say “by-reference” above because these statements are not always true for limited private types whose underlying type is nonlimited (unfortunately).

For other parameters of other types, it is unspecified whether the parameter is passed by copy or by reference.

**Discussion:** There is no need to incorporate the discussion of AI83-00178, which requires pass-by-copy for certain kinds of actual parameters, while allowing pass-by-reference for others. This is because we explicitly indicate that a function creates an anonymous constant object for its result, unless the type is a return by-reference type (see 6.5). We also provide a special dispensation for instances of Unchecked_Conversion to return by reference, even if the result type is not a return by-reference type (see 13.9).

If one name denotes a part of a formal parameter, and a second name denotes a part of a distinct formal parameter or an object that is not part of a formal parameter, then the two names are considered distinct access paths. If an object is of a type for which the parameter passing mechanism is not specified and is not an explicitly aliased parameter, then it is a bounded error to assign to the object via one access path, and then read the value of the object via a distinct access path, unless the first access path denotes a part of a formal parameter that no longer exists at the point of the second access [(due to leaving the corresponding callable construct).] The possible consequences are that Program_Error is raised, or the newly assigned value is read, or some old value of the object is read.

**Discussion:** For example, if we call “P(X => Global_Variable, Y => Global_Variable)”, then within P, the names “X”, “Y”, and “Global_Variable” are all distinct access paths. If Global_Variable’s type is neither pass-by-copy nor pass-by-reference, then it is a bounded error to assign to Global_Variable and then read X or Y, since the language does not specify whether the old or the new value would be read. On the other hand, if Global_Variable’s type is pass-by-copy, then the old value would always be read, and there is no error. Similarly, if Global_Variable’s type is defined by the language to be pass-by-reference, then the new value would always be read, and again there is no error.
Reason: We are saying assign here, not update, because updating any subcomponent is considered to update the enclosing object.

The “still exists” part is so that a read after the subprogram returns is OK.

If the parameter is of a by-copy type, then there is no issue here — the formal is not a view of the actual. If the parameter is of a by-reference type, then the programmer may depend on updates through one access path being visible through some other access path, just as if the parameter were of an access type.

Implementation Note: The implementation can keep a copy in a register of a parameter whose parameter-passing mechanism is not specified. If a different access path is used to update the object (creating a bounded error situation), then the implementation can still use the value of the register, even though the in-memory version of the object has been changed. However, to keep the error properly bounded, if the implementation chooses to read the in-memory version, it has to be consistent — it cannot then assume that something it has proven about the register is true of the memory location. For example, suppose the formal parameter is L, the value of L(6) is now in a register, and L(6) is used in an indexed_component as in “A(L(6)) := 99;”, where A has bounds 1..3. If the implementation can prove that the value for L(6) in the register is in the range 1..3, then it need not perform the constraint check if it uses the register value. However, if the memory value of L(6) has been changed to 4, and the implementation uses that memory value, then it had better not alter memory outside of A.

Implementation Note: The implementation can keep a copy in a register of a parameter whose parameter-passing mechanism is not specified. If a different access path is used to update the object (creating a bounded error situation), then the implementation can still use the value of the register, even though the in-memory version of the object has been changed. However, to keep the error properly bounded, if the implementation chooses to read the in-memory version, it has to be consistent — it cannot then assume that something it has proven about the register is true of the memory location. For example, suppose the formal parameter is L, the value of L(6) is now in a register, and L(6) is used in an indexed_component as in “A(L(6)) := 99;”, where A has bounds 1..3. If the implementation can prove that the value for L(6) in the register is in the range 1..3, then it need not perform the constraint check if it uses the register value. However, if the memory value of L(6) has been changed to 4, and the implementation uses that memory value, then it had better not alter memory outside of A.

Reason: We do not want to go so far as to say that the mere presence of aliasing is wrong. We wish to be able to write the following sorts of things in standard Ada:

```ada
procedure Move ( Source : in String;
Target : out String;
Drop : in Truncation := Error;
Justify : in Alignment := Left;
Pad : in Character := Space);
-- Copies elements from Source to Target (safely if they overlap)
```

This is from the standard string handling package. It would be embarrassing if this couldn't be written in Ada!

Reason: We do not want to go so far as to say that the mere presence of aliasing is wrong. We wish to be able to write the following sorts of things in standard Ada:

```ada
procedure Move ( Source : in String;
Target : out String;
Drop : in Truncation := Error;
Justify : in Alignment := Left;
Pad : in Character := Space);
-- Copies elements from Source to Target (safely if they overlap)
```

This is from the standard string handling package. It would be embarrassing if this couldn't be written in Ada!

The “then” before “read” in the rule implies that the implementation can move a read to an earlier place in the code, but not to a later place after a potentially aliased assignment. Thus, if the subprogram reads one of its parameters into a local variable, and then updates another potentially aliased one, the local copy is safe — it is known to have the old value. For example, the above-mentioned Move subprogram can be implemented by copying Source into a local variable before assigning into Target.

For an assignment_statement assigning one array parameter to another, the implementation has to check which direction to copy at run time, in general, in case the actual parameters are overlapping slices. For example:

```ada
procedure Copy(X : in out String; Y: String) is
begin
  X := Y;
end Copy;
```

It would be wrong for the compiler to assume that X and Y do not overlap (unless, of course, it can prove otherwise).

NOTES

6 A formal parameter of mode in is a constant view (see 3.3); it cannot be updated within the subprogram_body.

Extensions to Ada 83

The value of an out parameter may be read. An out parameter is treated like a declared variable without an explicit initial expression.

Wording Changes from Ada 83

Discussion of copy-in for parts of out parameters is now covered in 6.4.1, “Parameter Associations”.

The concept of a by-reference type is new to Ada 95.

We now cover in a general way in 3.7.2 the rule regarding erroneous execution when a discriminant is changed and one of the parameters depends on the discriminant.

Wording Changes from Ada 2005

Correction: Corrected so that limited derived types are by-reference only if their parent is by-reference.

Defined that explicitly aliased parameters (see 6.1) are always passed by reference.
6.3 Subprogram Bodies

[A subprogram_body specifies the execution of a subprogram.]

Syntax

\{AI95-00218-03\} \{AI05-0183-1\} subprogram_body ::= 
  [overriding_indicator]
  subprogram_specification 
  [aspect_specification] is 
  declarative_part 
  begin 
  handled_sequence_of_statements 
  end [designator];

If a designator appears at the end of a subprogram_body, it shall repeat the defining_designator of the subprogram_specification.

Legality Rules

[In contrast to other bodies,] a subprogram_body need not be the completion of a previous declaration[, in which case the body declares the subprogram]. If the body is a completion, it shall be the completion of a subprogram_declaration or generic_subprogram_declaration. The profile of a subprogram_body that completes a declaration shall conform fully to that of the declaration.

Static Semantics

A subprogram_body is considered a declaration. It can either complete a previous declaration, or itself be the initial declaration of the subprogram.

Dynamic Semantics

The elaboration of a nongeneric subprogram_body has no other effect than to establish that the subprogram can from then on be called without failing the Elaboration_Check.

Ramification: See 12.2 for elaboration of a generic body. Note that protected subprogram_bodies never get elaborated; the elaboration of the containing protected_body allows them to be called without failing the Elaboration_Check.

[The execution of a subprogram_body is invoked by a subprogram call.] For this execution the declarative_part is elaborated, and the handled_sequence_of_statements is then executed.

Examples

Example of procedure body:

procedure Push(E : in Element_Type; S : in out Stack) is 
begin 
  if S.Index = S.Size then 
    raise Stack_Overflow;
  else 
    S.Index := S.Index + 1;
    S.Space(S.Index) := E;
  end if;
end Push;
6.3 Subprogram Bodies

Example of a function body:

```ada
function Dot_Product(Left, Right : Vector) return Real is
    Sum : Real := 0.0;
    begin
        Check(Left'First = Right'First and Left'Last = Right'Last);
        for J in Left'Range loop
            Sum := Sum + Left(J)*Right(J);
        end loop;
        return Sum;
    end Dot_Product;
```

Extensions to Ada 83

11.1 A renaming declaration may be used instead of a subprogram body.

Wording Changes from Ada 83

11.2 The syntax rule for subprogram body now uses the syntactic category handled_sequence_of_statements.

11.3 The declarative part of a subprogram body is now required; that doesn't make any real difference, because a declarative part can be empty.

11.4 We have incorporated some rules from RM83-6.5 here.

11.5 RM83 forgot to restrict the definition of elaboration of a subprogram body to nongenerics.

Wording Changes from Ada 95

11.6 Overriding_indicator is added to subprogram body.

Extensions to Ada 2005

11.7 An optional aspect specification can be used in a subprogram body. This is described in 13.1.1.

6.3.1 Conformance Rules

[When subprogram profiles are given in more than one place, they are required to conform in one of four ways: type conformance, mode conformance, subtype conformance, or full conformance.]

Static Semantics

2/1 [8652/0011] {AI95-00117-01} [As explained in B.1, “Interfacing Aspects”, a convention can be specified for an entity.] Unless this International Standard states otherwise, the default convention of an entity is Ada. [For a callable entity or access-to-subprogram type, the convention is called the calling convention.] The following conventions are defined by the language:

3/3 • {AI05-0229-1} The default calling convention for any subprogram not listed below is Ada. The pragma Convention aspect, Import, or Export may be specified to override the default calling convention (see B.1)].

Ramification: See also the rule about renamings-as-body in 8.5.4.

3.1 The Intrinsic calling convention represents subprograms that are “built in” to the compiler. The default calling convention is Intrinsic for the following:

• an enumeration literal;
• a "=" operator declared implicitly due to the declaration of "=" (see 6.6);
• any other implicitly declared subprogram unless it is a dispatching operation of a tagged type;
• an inherited subprogram of a generic formal tagged type with unknown discriminants;

Reason: Consider:

285      13 December 2012 Conformance Rules

6.3.1

package P is
type Root is tagged null record;
procedure Proc(X: Root);
end P;
generic
type Formal<> is new Root with private;
package G is
...
end G;
package body G is
...
X: Formal := ...;
...
Proc(X); -- This is a dispatching call in Instance, because
-- the actual type for Formal is class-wide.
...
-- Proc'Access would be illegal here, because it is of
-- convention Intrinsic, by the above rule.
end G;
type Actual is new Root with ...;
procedure Proc(A: Actual);
package Instance is new G(Formal => Actual'Class);
-- It is legal to pass in a class-wide actual, because Formal
-- has unknown discriminants.

Within Instance, all calls to Proc will be dispatching calls, so Proc doesn't really exist in machine code, so we wish to avoid taking 'Access of it. This rule applies to those cases where the actual type might be class-wide, and makes these Intrinsic, thus forbidding 'Access.

• an attribute that is a subprogram;
• {AI95-00252-01} a subprogram declared immediately within a protected_body;
• {AI95-00252-01} a prefixed view of a subprogram (see 4.1.3).

Reason: The profile of a prefixed view is different than the “real” profile of the subprogram (it doesn't have the first parameter), so we don't want to be able to take 'Access of it, as that would require generating a wrapper of some sort.

[The Access attribute is not allowed for Intrinsic subprograms.]

Ramification: The Intrinsic calling convention really represents any number of calling conventions at the machine code level; the compiler might have a different instruction sequence for each intrinsic. That's why the Access attribute is disallowed. We do not wish to require the implementation to generate an out of line body for an intrinsic.

{AI05-0229-1} Whenever we wish to disallow the Access attribute in order to ease implementation, we make the subprogram Intrinsic. Several language-defined subprograms have "pragma Convention => (Intrinsic, ...)." An implementation might actually implement this as "pragma Import => True, Convention => (Intrinsic, ...)," if there is really no body, and the implementation of the subprogram is built into the code generator.

Subprograms declared in protected_bodies will generally have a special calling convention so as to pass along the identification of the current instance of the protected type. The convention is not protected since such local subprograms need not contain any “locking” logic since they are not callable via “external” calls; this rule prevents an access value designating such a subprogram from being passed outside the protected unit.

The “implicitly declared subprogram” above refers to predefined operators (other than the "=" of a tagged type) and the inherited subprograms of untagged types.

• The default calling convention is protected for a protected subprogram, and for an access-to-subprogram type with the reserved word protected in its definition.

• The default calling convention is entry for an entry.

• {AI95-00254-01} {AI95-00409-01} {AI05-0264-1} The calling convention for an anonymous access-to-subprogram parameter or anonymous access-to-subprogram result is protected if the reserved word protected appears in its definition; and otherwise, it is the convention of the subprogram that contains the parameter.

Ramification: The calling convention for other anonymous access-to-subprogram types is Ada.

• {8652/0011} {AI95-00117-01} [If not specified above as Intrinsic, the calling convention for any inherited or overriding dispatching operation of a tagged type is that of the corresponding

6.3.1 Conformance Rules

subprogram of the parent type. The default calling convention for a new dispatching operation of a tagged type is the convention of the type.

Reason: The first rule is officially stated in 3.9.2. The second is intended to make interfacing to foreign OOP languages easier, by making the default be that the type and operations all have the same convention.

13.a.1/1

{AI05-0229-1} Of these four conventions, only Ada and Intrinsic are allowed as a convention_identifier in the specification of an pragma Convention aspect Import, or Export.

14/3

Discussion: {AI05-0229-1} The names of the protected and entry calling conventions cannot be used in the specification of Convention interfacing pragmas. Note that protected and entry are reserved words.

15/2

{AI95-00409-01} Two profiles are type conformant if they have the same number of parameters, and both have a result if either does, and corresponding parameter and result types are the same, or, for access parameters or access results, corresponding designated types are the same, or corresponding designated profiles are type conformant.

15.a/2

Discussion: {AI95-00409-01} For anonymous access-to-object access parameters, the designated types have to be the same for type conformance, not the access types, since in general each access parameter has its own anonymous access type, created when the subprogram is called. Of course, corresponding parameters have to be either both access parameters or both not access parameters.

15.b/2

{AI95-00409-01} Similarly, for anonymous access-to-subprogram parameters, the designated profiles of the types, not the types themselves, have to be conformant.

16/3

{AI95-00318-02} {AI95-00409-01} {AI05-0142-4} Two profiles are mode conformant if they are type conformant, and corresponding parameters have identical modes, and, for access parameters or access result types, the designated subtypes statically match, or the designated profiles are subtype conformant.

16.1/3

• {AI05-0142-4} {AI05-0262-1} they are type conformant; and

16.2/3

• {AI05-0142-4} corresponding parameters have identical modes and both or neither are explicitly aliased parameters; and

16.3/3

• {AI05-0207-1} for corresponding access parameters and any access result type, the designated subtypes statically match and either both or neither are access-to-constant, or the designated profiles are subtype conformant.

17/3

{AI05-0239-1} Two profiles are subtype conformant if they are mode conformant, corresponding subtypes of the profile statically match, and the associated calling conventions are the same. The profile of a generic formal subprogram is not subtype conformant subtype conformant with any other profile.

17.a

Ramification:

18/3

{AI05-0134-1} {AI05-0262-1} Two profiles are fully conformant if they are subtype conformant subtype conformant, if they have access-to-subprogram results whose designated profiles are fully conformant, and for corresponding parameters: have the same names and have default_expressions that are fully conformant with one another.

18.1/3

• {AI05-0262-1} they have the same names; and

18.2/3

• {AI05-0046-1} both or neither have null_exclusions; and

18.3/3

• neither have default_expressions, or they both have default_expressions that are fully conformant with one another; and

18.4/3

• {AI05-0134-1} for access-to-subprogram parameters, the designated profiles are fully conformant.

18.a

Ramification: Full conformance requires subtype conformance, which requires the same calling conventions. However, the calling convention of the declaration and body of a subprogram or entry are always the same by definition.

Reason: {AI05-0046-1} The part about null_exclusions is necessary to prevent controlling parameters from having different exclusions, as such a parameter is defined to exclude null whether or not an exclusion is given.
The parts about access-to-subprogram parameters and results is necessary to prevent such types from having different default expressions in the specification and body of a subprogram. If that was allowed, it would be undefined which default_expression was used in a call of an access-to-subprogram parameter.

Two expressions are fully conformant if, [after replacing each use of an operator with the equivalent function_call]:

- each constituent construct of one corresponds to an instance of the same syntactic category in the other, except that an expanded name may correspond to a direct_name (or character_literal) or to a different expanded name in the other; and

- each direct_name, character_literal, and selector_name that is not part of the prefix of an expanded name in one denotes the same declaration as the corresponding direct_name, character_literal, or selector_name in the other; and

Ramification: Note that it doesn’t say “respectively” because a direct_name can correspond to a selector_name, and vice-versa, by the previous bullet. This rule allows the prefix of an expanded name to be removed, or replaced with a different prefix that denotes a renaming of the same entity. However, it does not allow a direct_name or selector_name to be replaced with one denoting a distinct renaming (except for direct_names and selector_names in prefixes of expanded names). Note that calls using operator notation are equivalent to calls using prefix notation.

Given the following declarations:

```ada
package A is
    function F(X : Integer := 1) return Boolean;
end A;

{AI05-0005-1} with A;

package B is
    package A_View renames A;
    function F_View(X : Integer := 9999) return Boolean renames A.F;
end B;

with A, B; use A, B;

procedure Main is ...
```

Within Main, the expressions “F”, “A.F”, “B.A_View.F”, and “A_View.F” are all fully conformant with one another. However, “F” and “F_View” are not fully conformant. If they were, it would be bad news, since the two denoted views have different default_expressions.

- `{8652/0018} {AI95-00175-01} {AI05-0092-1} each attribute_designator in one is must be the same as the corresponding attribute_designator in the other; and

- each primary that is a literal in one has the same value as the corresponding literal in the other.

Ramification: The literals may be written differently.

Ramification: Note that the above definition makes full conformance a transitive relation.

Two known_discriminant_parts are fully conformant if they have the same number of discriminants, and discriminants in the same positions have the same names, statically matching subtypes, and default_expressions that are fully conformant with one another.

Two discrete_subtype_definitions are fully conformant if they are both subtype_indications or are both ranges, the subtype_marks (if any) denote the same subtype, and the corresponding simple_expressions of the ranges (if any) fully conform.

Ramification: In the subtype_indication case, any ranges have to be corresponding; that is, two subtype_indications cannot conform unless both or neither has a range.

Discussion: This definition is used in 9.5.2, “Entries and Accept Statements” for the conformance required between the discrete_subtype_definitions of an entry_declaration for a family of entries and the corresponding entry_index_specification of the entry_body.

The prefixed view profile of a subprogram is the profile obtained by omitting the first parameter of that subprogram. There is no prefixed view profile for a parameterless subprogram. For the purposes of defining subtype and mode conformance, the convention of a prefixed view profile is considered to match that of either an entry or a protected operation.
Discussion: This definition is used to define how primitive subprograms of interfaces match operations in task and protected type definitions (see 9.1 and 9.4).

Reason: The weird rule about conventions is pretty much required for synchronized interfaces to make any sense. There will be wrappers all over the place for interfaces anyway. Of course, this doesn't imply that entries have the same convention as protected operations.

Implementation Permissions

An implementation may declare an operator declared in a language-defined library unit to be intrinsic.

Extensions to Ada 83

The rules for full conformance are relaxed — they are now based on the structure of constructs, rather than the sequence of lexical elements. This implies, for example, that "(X, Y: T)" conforms fully with "(X: T; Y: T)" and "(X: T)" conforms fully with "(X: in T)".

Wording Changes from Ada 95

Corrigendum: Clarified that the default convention is Ada. Also clarified that the convention of a primitive operation of a tagged type is the same as that of the type.

Corrigendum: Added wording to ensure that two attributes conform only if they have the same attribute_designator.

Defined the calling convention for anonymous access-to-subprogram types and for prefixed views of subprograms (see 4.1.3).

Defined the conformance of access result types (see 6.1).

Defined the prefixed view profile of subprograms for later use.

Defined the conformance of anonymous access-to-subprogram parameters.

Incompatibilities With Ada 2005

Correction: Now require null_exclusion to match for full conformance. While this is technically incompatible with Ada 2005 as defined by Amendment 1, it is a new Ada 2005 feature and it is unlikely that users have been intentionally taking advantage of the ability to write mismatching exclusions. In any case, it is easy to fix: add a null_exclusion where needed for conformance.

Correction: Now require full conformance of anonymous access-to-subprogram parameters and results for full conformance. This is necessary so that there is no confusion about the default expression that is used for a call. While this is technically incompatible with Ada 2005 as defined by Amendment 1, it is a new Ada 2005 feature and it is unlikely that users have been intentionally taking advantage and writing different default expressions. In any case, it is easy to fix: change any default expressions that don't conform so that they do conform.

Correction: Now include the presence or absence of constant in access parameters to be considered when checking mode conformance. This is necessary to prevent modification of constants. While this is technically incompatible with Ada 2005 as defined by Amendment 1, it is a new Ada 2005 feature and it is unlikely that users have been intentionally taking advantage and writing mismatching access types.

Wording Changes from Ada 2005

Explicitly aliased parameters are included as part of mode conformance (since it affects the parameter passing mechanism).

6.3.2 Inline Expansion of Subprograms

Subprograms may be expanded in line at the call site.

Syntax

The form of a pragma Inline, which is a program unit pragma (see 10.1.5), is as follows:

pragma Inline(name, name);

Legality Rules

{AI05-0229-1} The pragma shall apply to one or more callable entities or generic subprograms.

Static Semantics

{AI05-0229-1} If a pragma Inline applies to a callable entity or a generic subprogram, the following language-defined representation aspect may be specified: this indicates that inline expansion is desired for all calls to all instances of that generic subprogram.

Inline

The type of aspect Inline is Boolean. When aspect Inline is True for a callable entity, inline expansion is desired for all calls to that entity. When aspect Inline is True for a generic subprogram, inline expansion is desired for all calls to all instances of that generic subprogram.

If directly specified, the aspect definition shall be a static expression. [This aspect is never inherited:] if not directly specified, the aspect is False.

Aspect Description for Inline: For efficiency, Inline calls are requested for a subprogram.

Ramification: {AI05-0229-1} Note that inline expansion is desired no matter what name is used in the call. This allows one to request inlining for only one of several overloaded subprograms as follows:

This paragraph was deleted. package IO is
  procedure Put(X : in Integer);
  procedure Put(X : in String);
  procedure Put(X : in Character);
private
  procedure Character_Put(X : in Character) renames Put;
end IO;

This paragraph was deleted. with IO use IO;

procedure Main is
  I : Integer;
  C : Character;
begin
  Put(C); -- Inline expansion is desired.
  Put(I); -- Inline expansion is NOT desired.
end Main;

Ramification: {AI05-0229-1} The meaning of a subprogram can be changed by inline expansion as requested by aspect pragma Inline only in the presence of failing checks (see 11.6).

Implementation Permissions

{AI05-0229-1} For each call, an implementation is free to follow or to ignore the recommendation determined by the Inline aspect pragma.

Ramification: Note, in particular, that the recommendation cannot always be followed for a recursive call, and is often infeasible for entries. Note also that the implementation can inline calls even when no such desire was expressed via the Inline aspect pragma, so long as the semantics of the program remains unchanged.

{AI05-00309-01} {AI05-0229-1} An implementation may allow a pragma Inline that has an argument which is a direct name denoting a subprogram body of the same declarative part.

Reason: This is allowed for Ada 83 compatibility. This is only a permission as this usage is considered obsolescent.

Discussion: We only need to allow this in declarative parts, because a body is only allowed in another body, and these all have declarative parts.

NOTES

7 {AI05-0229-1} The name in a pragma Inline can denote more than one entity in the case of overloading. Such a pragma applies to all of the denoted entities.
6.4 Subprogram Calls

A subprogram call is either a procedure_call_statement or a function_call; [it invokes the execution of the subprogram_body. The call specifies the association of the actual parameters, if any, with formal parameters of the subprogram.]

Syntax

procedure_call_statement ::= 
  procedure_name;  
  | procedure_prefix actual_parameter_part; 

function_call ::=  
  function_name  
  | function_prefix actual_parameter_part 

To be honest: {AI05-0005-1} For the purpose of non-syntax rules, infix operator calls are considered function_calls. See 6.6.

actual_parameter_part ::=  
  (parameter_association {, parameter_association})

parameter_association ::=  
  [formal_parameter_selector_name =>] explicit_actual_parameter

explicit_actual_parameter ::= expression | variable_name

A parameter_association is named or positional according to whether or not the formal_parameter_selector_name is specified. Any positional associations shall precede any named associations. Named associations are not allowed if the prefix in a subprogram call is an attribute-reference.

Ramification: This means that the formal parameter names used in describing predefined attributes are to aid presentation of their semantics, but are not intended for use in actual calls.

Name Resolution Rules

The name or prefix given in a procedure_call_statement shall resolve to denote a callbable entity that is a procedure, or an entry renamed as (viewed as) a procedure. The name or prefix given in a function_call shall resolve to denote a callbable entity that is a function. The name or prefix shall not resolve to denote an abstract subprogram unless it is also a dispatching subprogram. [When there is an actual_parameter_part, the prefix can be an implicit_dereference of an access-to-subprogram value.]
Discussion: {AI95-00310-01} This rule is talking about dispatching operations (which is a static concept) and not about dispatching calls (which is a dynamic concept).

Ramification: The function can be an operator, enumeration literal, attribute that is a function, etc.

A subprogram call shall contain at most one association for each formal parameter. Each formal parameter without an association shall have a default_expression (in the profile of the view denoted by the name or prefix). [This rule is an overloading rule (see 8.6).]

Proof: {AI05-0240-1} All Name Resolution Rules are overloading rules, see 8.6.

Dynamic Semantics

{AI95-00345-01} For the execution of a subprogram call, the name or prefix of the call is evaluated, and each parameter_association is evaluated (see 6.4.1). If a default_expression is used, an implicit parameter_association is assumed for this rule. These evaluations are done in an arbitrary order. The subprogram_body is then executed, or a call on an entry or protected subprogram is performed (see 3.9.2).

Discussion: The implicit association for a default is only for this run-time rule. At compile time, the visibility rules are applied to the default at the place where it occurs, not at the place of a call.

To be honest: If the subprogram is inherited, see 3.4, “Derived Types and Classes”.

If the subprogram is protected, see 9.5.1, “Protected Subprograms and Protected Actions”.

If the subprogram is really a renaming of an entry, see 9.5.3, “Entry Calls”.

{AI95-00345-01} If the subprogram is implemented by an entry or protected subprogram, it will be treated as a dispatching call to the corresponding entry (see 9.5.3, “Entry Calls”) or protected subprogram (see 9.5.1, “Protected Subprograms and Protected Actions”).

{AI95-00348-01} Normally, the subprogram_body that is executed by the above rule is the one for the subprogram being called. For an enumeration literal, implicitly declared (but noninherited) subprogram, null procedure, or an attribute that is a subprogram, an implicit body is assumed. For a dispatching call, 3.9.2, “Dispatching Operations of Tagged Types” defines which subprogram_body is executed.

{AI95-00407-01} A function_call denotes a constant, as defined in 6.5; the nominal subtype of the constant is given by the nominal_result subtype of the function result.

Examples of procedure calls:

Traverse_Tree; -- see 6.1
Print_Header(128, Title, True); -- see 6.1
Switch(From => X, To => Next); -- see 6.1
Print_Header(128, Header => Title, Center => True); -- see 6.1
Print_Header(Header => Title, Center => True, Pages => 128); -- see 6.1

Examples
Examples of function calls:

- Dot_Product(U, V)  -- see 6.1 and 6.3
- Clock             -- see 9.6
- F.all             -- presuming F is of an access-to-subprogram type — see 3.10

Examples of procedures with default expressions:

```ada
procedure Activate(Process : in Process_Name;
                   After   : in Process_Name := No_Process;
                   Wait    : in Duration := 0.0;
                   Prior   : in Boolean := False);
```

```
procedure Pair(Left, Right : in Person_Name := new Person(M));  -- see 3.10.1
```

Examples of their calls:

- Activate(X);
- Activate(X, After => Y);
- Activate(X, Wait => 60.0, Prior => True);
- Activate(X, Y, 10.0, False);

```ada
{AI05-0299-1} procedure Pair(Left => new Person(F), Right => new Person(M));
```

NOTES

- If a default_expression is used for two or more parameters in a multiple parameter_specification, the default_-
  expression is evaluated once for each omitted parameter. Hence in the above examples, the two calls of Pair are equivalent.

Examples of overloaded subprograms:

```ada
procedure Put(X : in Integer);
procedure Put(X : in String);
procedure Set(Tint   : in Color);
procedure Set(Signal : in Light);
```

Examples of their calls:

- Put(28);
- Put("no possible ambiguity here");
- Set(Tint => Red);
- Set(Signal => Red);
- Set(Color'(Red));

- -- Set(Res) would be ambiguous since Res may
denote a value either of type Color or of type Light

Wording Changes from Ada 83

- We have gotten rid of parameters “of the form of a type conversion” (see RM83-6.4.1(3)). The new view semantics of
  type_conversions allows us to use normal type_conversions instead.
- We have moved wording about run-time semantics of parameter associations to 6.4.1.
- We have moved wording about raising Program_Error for a function that falls off the end to here from RM83-6.5.

Extensions to Ada 95

- Nondispatching abstract operations are no longer considered when resolving a subprogram call. That makes it possible to use abstract to "undefine" a predefined operation for an untagged type. That's especially helpful when defining custom arithmetic packages.

Wording Changes from Ada 95

- Changed the definition of the nominal subtype of a function_call to use the nominal subtype wording of 6.1, to take into account null_exclusions and access result types.
6.4.1 Parameter Associations

[A parameter association defines the association between an actual parameter and a formal parameter.]

Language Design Principles

The parameter passing rules for out parameters are designed to ensure that the parts of a type that have implicit initial values (see 3.3.1) don't become “de-initialized” by being passed as an out parameter.

For explicitly aliased parameters of functions, we will ensure at the call site that a part of the parameter can be returned as part of the function result without creating a dangling pointer. We do this with accessibility checks at the call site that all actual objects of explicitly aliased parameters live at least as long as the function result; then we can allow them to be returned as access discriminants or anonymous access results, as those have the master of the function result.

Name Resolution Rules

The formal parameter selector name of a named parameter association shall resolve to denote a parameter specification of the view being called; this is the formal parameter of the association. The formal parameter for a positional parameter association is the parameter with the corresponding position in the formal part of the view being called.

To be honest: For positional parameters, the “corresponding position” is calculated after any transformation of prefixed views.

The actual parameter is either the explicit actual parameter given in a parameter association for a given formal parameter, or the corresponding default expression if no parameter association is given for the formal parameter. The expected type for an actual parameter is the type of the corresponding formal parameter.

To be honest: The corresponding default expression is the one of the corresponding formal parameter in the profile of the view denoted by the name or prefix of the call.

If the mode is in, the actual is interpreted as an expression; otherwise, the actual is interpreted only as a name, if possible.

Ramification: This formally resolves the ambiguity present in the syntax rule for explicit actual parameter. Note that we don't actually require that the actual be a name if the mode is not in; we do that below.

Legality Rules

If the mode is in out or out, the actual shall be a name that denotes a variable.

Discussion: We no longer need “or a type_conversion whose argument is the name of a variable,” because a type_conversion is now a name, and a type_conversion of a variable is a variable.

Reason: The requirement that the actual be a (variable) name is not an overload resolution rule, since we don't want the difference between expression and name to be used to resolve overloading. For example:

```ada
procedure Print(X : in Integer; Y : in Boolean := True);
procedure Print(Z : in out Integer);

Print(3);  -- Ambiguous!
```

The above call to Print is ambiguous even though the call is not compatible with the second Print which requires an actual that is a (variable) name (“3” is an expression, not a name). This requirement is a legality rule, so overload resolution fails before it is considered, meaning that the call is ambiguous.

If the formal parameter is an explicitly aliased parameter, the type of the actual parameter shall be tagged or the actual parameter shall be an aliased view of an object. Further, if
the formal parameter subtype \( F \) is untagged; the type of the actual parameter associated with an access parameter shall be convertible (see 4.6) to its anonymous access type.

- the subtype \( F \) shall statically match the nominal subtype of the actual object; or
- the subtype \( F \) shall be unconstrained, discriminated in its full view, and unconstrained in any partial view.

**Ramification:** Tagged objects (and tagged aggregates for in parameters) do not need to be aliased. This matches the behavior of unaliased formal parameters of tagged types, which allow 'Access to be taken of the formal parameter regardless of the form of the actual parameter.

**Reason:** We need the subtype check on untagged actual parameters so that the requirements of 'Access are not lost. 'Access makes its checks against the nominal subtype of its prefix, and parameter passing can change that subtype. But we don't want this parameter passing to change the objects that would be allowed as the prefix of 'Access. This is particularly important for arrays, where we don't want to require any additional implementation burden.

**AI05-0142-4** {AI05-0234-1} In a function call, the accessibility level of the actual object for each explicitly aliased parameter shall not be statically deeper than the accessibility level of the master of the call (see 3.10.2).

**Discussion:** Since explicitly aliased parameters are either tagged or required to be objects, there is always an object (possibly anonymous) to talk about. This is discussing the static accessibility level of the actual object; it does not depend on any runtime information (for instance when the actual object is a formal parameter of another subprogram, it does not depend on the actual parameter of that other subprogram).

**Ramification:** This accessibility check (and its dynamic cousin as well) can only fail if the function call is used to directly initialize a built-in-place object with a master different than that enclosing the call. The only place all of those conditions exist is in the initializer of an allocator; in all other cases this check will always pass.

**AI05-0144-2** Two names are known to denote the same object if:

- both names statically denote the same stand-alone object or parameter; or
- both names are selected components, their prefixes are known to denote the same object, and their selector names denote the same component; or
- both names are dereferences (implicit or explicit) and the dereferenced names are known to denote the same object; or
- both names are indexed components, their prefixes are known to denote the same object, and each of the pairs of corresponding index values are either both static expressions with the same static value or both names that are known to denote the same object; or
- both names are slices, their prefixes are known to denote the same object, and the two slices have statically matching index constraints; or
- one of the two names statically denotes a renaming declaration whose renamed object name is known to denote the same object as the other, the prefix of any dereference within the renamed object name is not a variable, and any expression within the renamed object name contains no references to variables nor calls on nonstatic functions.

**Reason:** This exposes known renamings of slices, indexing, and so on to this definition. In particular, if we have

\[
\begin{align*}
    C : \text{Character} & \text{ renames } S(1); \\
    \text{then } C \text{ and } S(1) & \text{ are known to denote the same object.}
\end{align*}
\]

We need the requirement that no variables occur in the prefixes of dereferencess and in (index) expressions of the renamed object in order to avoid problems from later changes to those parts of renamed names. Consider:

\[
\begin{align*}
    \text{type } \text{Ref is access Some Type; } \\
    \text{Ptr : } \text{Ref} & := \text{new Some Type'}(...)\text{; } \\
    X : \text{Some Type} & \text{ renames } \text{Ptr.all; } \\
    \text{begin } \\
    \text{Ptr} := \text{new Some Type'}(...)\text{; } \\
    P \text{'Func With Out Params (Ptr.all, X'); } \\
    \text{end} \\
    \text{X and } \text{Ptr.all} & \text{ should not be known to denote the same object, since they denote different allocated objects (and this is not an unreasonable thing to do).}
\end{align*}
\]
To be honest: The exclusion of variables from renamed object names is not enough to prevent altering the value of the name or expression by another access path. For instance, both in parameters passed by reference and access-to-constant values can designate variables. For the intended use of "known to be the same object", this is OK, the modification via another access path is very tricky and it is OK to reject code that would be buggy except for the tricky code. Assuming Element is an elementary type, consider the following example:

```ada
package Global is
   type Tagged_Type is new System.Text.New_Item_Vector_Type;
   type Nat is Integer;
   type Element is new System.Text.New_Item_Vector_Type.
   N : Nat := 1;
   Global : Tagged_Type;
   X : Element := Global.C;
begin
   Global.C := Global.C + 1;
   Swap (X, Global.Array (Param.C));
end;
```

The rules will flag the call of procedure Swap as illegal, since `X` and `Global.Array (Param.C)` are known to denote the same object (even though they will actually represent different objects if `Param = Global`). But this is only incorrect if the parameter actually is `Global` and not some other value; the error could exist for some calls. So this flagging seems harmless.

Similar examples can be constructed using stand-alone composite constants with controlled or immutably limited components, and (as previously noted) with dereferences of access-to-constant values. Even when these examples flag a call incorrectly, that call depends on very tricky code (modifying the value of a constant); the code is likely to confuse future maintainers as well and thus we do not mind rejecting it.

Discussion: Whether or not names or prefixes are known to denote the same object is determined statically. If the name contains some dynamic portion other than a dereference, indexed component, or slice, it is not "known to denote the same object".

These rules make no attempt to handle slices of objects that are known to be the same when the slices have dynamic bounds (other than the trivial case of bounds being defined by the same subtype), even when the bounds could be proven to be the same, as it is just too complex to get right and these rules are intended to be conservative.

Ramification: "Known to denote the same object" is intended to be an equivalence relationship, that is, it is reflexive, symmetric, and transitive. We believe this follows from the rules. For instance, given the following declarations:

```ada
S : String(1..10);
ONE : constant Natural := 1;
R : Character renames S(1);
```

the names `R` and `S(1)` are known to denote the same object by the sixth bullet, and `S(1)` and `S(ONE)` are known to denote the same object by the fourth bullet, so using the sixth bullet on `R` and `S(ONE)`, we simply have to test `S(1)` vs. `S(ONE)`, which we already know denote the same object.

A105-0144-2 Two names are known to refer to the same object if:

- The two names are known to denote the same object; or
- One of the names is a selected component, indexed component, or slice and its prefix is known to refer to the same object as the other name; or
- One of the two names statically denotes a renaming declaration whose renamed object name is known to refer to the same object as the other name.

Reason: This ensures that names Prefix.Com and Prefix are known to refer to the same object for the purposes of the rules below. This intentionally does not include dereferences; we only want to worry about accesses to the same object, and a dereference changes the object in question. (There is nothing shared between an access value and the object it designates.)

A105-0144-2 If a call `C` has two or more parameters of mode `in out` or `out` that are of an elementary type, then the call is legal only if:

- For each name `N` that is passed as a parameter of mode `in out` or `out` to the call `C`, there is no other name among the other parameters of mode `in out` or `out` to `C` that is known to denote the same object.

To be honest: This means visibly an elementary type; it does not include partial views of elementary types (partial views are always composite). That's necessary to avoid having Legality Rules depend on the contents of the private part.

A105-0144-2 If a construct `C` has two or more direct constituents that are names or expressions whose evaluation may occur in an arbitrary order, at least one of which contains a function call with an `in out` or `out` parameter, then the construct is legal only if:

6.4.1 Parameter Associations

Ramification: All of the places where the language allows an arbitrary order can be found by looking in the index under “arbitrary order, allowed”. Note that this listing includes places that don't involve names or expressions (such as checks or finalization).

For each name \( N \) that is passed as a parameter of mode \texttt{in out} or \texttt{out} to some inner function call \( C2 \) (not including the construct \( C \) itself), there is no other \texttt{name} anywhere within a direct constituent of the construct \( C \) other than the one containing \( C2 \), that is known to refer to the same object.

Ramification: This requirement cannot fail for a procedure or entry call alone; there must be at least one function with an \texttt{in out} or \texttt{out} parameter called as part of a parameter expression of the call in order for it to fail.

Reason: These rules prevent obvious cases of dependence on the order of evaluation of names or expressions. Such dependence is usually a bug, and in any case, is not portable to another implementation (or even another optimization setting).

In the case that the top-level construct \( C \) is a call, these rules do not require checks for most \texttt{in out} parameters, as the rules about evaluation of calls prevent problems. Similarly, we do not need checks for short circuit operations or other operations with a defined order of evaluation. The rules about arbitrary order (see 1.1.4) allow evaluating parameters and writing parameters back in an arbitrary order, but not interleaving of evaluating parameters of one call with writing parameters back from another — that would not correspond to any allowed sequential order.

{\AI05-0144-2} For the purposes of checking this rule:

- For an array \texttt{aggregate}, an \texttt{expression} associated with a \texttt{discrete choice list} that has two or more discrete choices, or that has a nonstatic range, is considered as two or more separate occurrences of the \texttt{expression};

- For a record \texttt{aggregate}:
  - The \texttt{expression} of a \texttt{record component association} is considered to occur once for each associated component; and
  - The \texttt{default expression} for each \texttt{record component association} with \texttt{<>} for which the associated component has a \texttt{default expression} is considered part of the \texttt{aggregate};

- For a call, any \texttt{default expression} evaluated as part of the call is considered part of the call.

{\AI05-0144-2} For the purposes of checking this rule:

- For a record \texttt{aggregate}:
  - The \texttt{expression} of a \texttt{record component association} is considered to occur once for each associated component; and
  - The \texttt{default expression} for each \texttt{record component association} with \texttt{<>} for which the associated component has a \texttt{default expression} is considered part of the \texttt{aggregate};

- For a call, any \texttt{default expression} evaluated as part of the call is considered part of the call.

Ramification: We do not check expressions that are evaluated only because of a component initialized by default in an \texttt{aggregate} (via \texttt{<>}).

Dynamic Semantics

For the evaluation of a \texttt{parameter association}:

- The actual parameter is first evaluated.
- For an access parameter, the \texttt{access definition} is elaborated, which creates the anonymous access type.
- For a parameter [(of any mode)] that is passed by reference (see 6.2), a view conversion of the actual parameter to the nominal subtype of the formal parameter is evaluated, and the formal parameter denotes that conversion.

Discussion: We are always allowing sliding, even for \texttt{in out} by-reference parameters.

- For an \texttt{in} or \texttt{in out} parameter that is passed by copy (see 6.2), the formal parameter object is created, and the value of the actual parameter is converted to the nominal subtype of the formal parameter and assigned to the formal.

Ramification: The conversion mentioned here is a value conversion.

- For an \texttt{out} parameter that is passed by copy, the formal parameter object is created, and:
  - \{\AI05-0153-3\} \{\AI05-0196-1\} For an access type, the formal parameter is initialized from the value of the actual, without checking that the value satisfies any constraint, any predicate, or any exclusion of the null value constraint check;
Parameter Associations

Reason: This preserves the Language Design Principle that an object of an access type is always initialized with a "reasonable" value.

- {AI05-0153-3} {AI05-0228-1} For a scalar type that has the Default Value aspect specified, the formal parameter is initialized from the value of the actual, without checking that the value satisfies any constraint or any predicate;

  Reason: This preserves the Language Design Principle that all objects of a type with an implicit initial value are initialized. This is important so that a programmer can guarantee that all objects of a scalar type have a valid value with a carefully chosen Default Value.

  Implementation Note: This rule means that out parameters of a subtype T with a specified Default Value need to be large enough to support any possible value of the base type of T. In contrast, a type that does not have a Default Value only need support the size of the subtype (since no values are passed in).

- For a composite type with discriminants or that has implicit initial values for any subcomponents (see 3.3.1), the behavior is as for an in out parameter passed by copy.

  Reason: This ensures that no part of an object of such a type can become "de-initialized" by being part of an out parameter.

  Ramification: This includes an array whose component type is an access type, and a record type with a component that has a default_expression, among other things.

- For any other type, the formal parameter is uninitialized. If composite, a view conversion of the actual parameter to the nominal subtype of the formal is evaluated [(which might raise Constraint_Error)], and the actual subtype of the formal is that of the view conversion. If elementary, the actual subtype of the formal is given by its nominal subtype.

  Ramification: {AI05-0228-1} This case covers scalar types that do not have Default Value specified, and composite types whose subcomponent's subtypes do not have any implicit initial values. The view conversion for composite types ensures that if the lengths don't match between an actual and a formal array parameter, the Constraint_Error is raised before the call, rather than after.

- {AI05-0142-4} {AI05-0234-1} In a function call, for each explicitly aliased parameter, a check is made that the accessibility level of the master of the actual object is not deeper than that of the master of the call (see 3.10.2).

  Ramification: If the actual object to a call C is a formal parameter of some function call F, no dynamic check against the master of the actual parameter of F is necessary. Any case which could fail the dynamic check is already statically illegal (either at the call site of F, or at the call site C). This is important, as it would require nasty distributed overhead to accurately know the dynamic accessibility of a formal parameter (all tagged and explicitly aliased parameters would have to carry accessibility levels).

A formal parameter of mode in out or out with discriminants is constrained if either its nominal subtype or the actual parameter is constrained.

After normal completion and leaving of a subprogram, for each in out or out parameter that is passed by copy, the value of the formal parameter is converted to the subtype of the variable given as the actual parameter and assigned to it. These conversions and assignments occur in an arbitrary order.

Ramification: The conversions mentioned above during parameter passing might raise Constraint_Error — (see 4.6).

Ramification: If any conversion or assignment as part of parameter passing propagates an exception, the exception is raised at the place of the subprogram call; that is, it cannot be handled inside the subprogram_body.

Proof: Since these checks happen before or after executing the subprogram_body, the execution of the subprogram_body does not dynamically enclose them, so it can't handle the exceptions.

Discussion: The variable we're talking about is the one denoted by the variable name given as the explicit_actual_parameter. If this variable_name is a type_conversion, then the rules in 4.6 for assigning to a view conversion apply. That is, if X is of subtype S1, and the actual is S2(X), the above-mentioned conversion will convert to S2, and the one mentioned in 4.6 will convert to S1.

Erroneous Execution

{AI05-0008-1} If the nominal subtype of a formal parameter with discriminants is constrained or indefinite, and the parameter is passed by reference, then the execution of the call is erroneous if the value
of any discriminant of the actual is changed while the formal parameter exists (that is, before leaving the corresponding callable construct).

Extensions to Ada 83

18.a In Ada 95, a program can rely on the fact that passing an object as an out parameter does not “de-initialize” any parts of the object whose subtypes have implicit initial values. (This generalizes the RM83 rule that required copy-in for parts that were discriminants or of an access type.)

Wording Changes from Ada 83

18.b3 \{AI05-0299-1\} We have eliminated the subclause on Default Parameters, as it is subsumed by earlier clauses and subclauses.

Inconsistencies With Ada 2005

18.c3 \{AI05-0196-1\} Correction: Clarified that out parameters of an access type are not checked for null exclusions when they are passed in (which is similar to the behavior for constraints). This was unspecified in Ada 2005, so a program which depends on the behavior of an implementation which does check the exclusion may malfunction. But a program depending on an exception being raised is unlikely.

Incompatibilities With Ada 2005

18.d3 \{AI05-0144-2\} Additional rules have been added to make illegal passing the same elementary object to more than one in out or out parameters of the same call. In this case, the result in the object could depend on the compiler version, optimization settings, and potentially the phase of the moon, so this check will mostly reject programs that are nonportable and could fail with any change. Even when the result is expected to be the same in both parameters, the code is unnecessarily tricky. Programs which fail this new check should be rare and are easily fixed by adding a temporary object.

Wording Changes from Ada 2005

18.e3 \{AI05-0008-1\} Correction: A missing rule was added to cover cases that were missed in Ada 95 and Ada 2005; specifically, that an in parameter passed by reference might have its discriminants changed via another path. Such cases are erroneous as requiring compilers to detect such errors would be expensive, and requiring such cases to work would be a major change of the user model (in parameters with discriminants could no longer be assumed constant). This is not an inconsistency, as compilers are not required to change any current behavior.

18.f3 \{AI05-0102-1\} Correction: Moved implicit conversion Legality Rule to 8.6.

18.g3 \{AI05-0118-1\} Correction: Added a definition for positional parameters, as this is missing from Ada 95 and later.

18.h3 \{AI05-0142-4\} Rules have been added defining the legality and dynamic checks needed for explicitly aliased parameters (see 6.1).

18.i3 \{AI05-0144-2\} Additional rules have been added such that passing an object to an in out or out parameter of a function is illegal if it is used elsewhere in a construct which allows evaluation in an arbitrary order. Such calls are not portable (since the results may depend on the evaluation order), and the results could even vary because of optimization settings and the like. Thus they've been banned.

6.5 Return Statements

1/2 \{AI95-00318-02\} A simple_return_statement or extended_return_statement (collectively called a return_statement) is used to complete the execution of the innermost enclosing subprogram_body, entry_body, or accept_statement.

Syntax

2/2 \{AI95-00318-02\} simple_return_statement :: = return [expression];

2.1/3 \{AI05-0277-1\} extended_return_object_declaration :: =

   defining_identifier : [aliased][constant] return_subtype_indication ::= expression
The result subtype of a function is the subtype denoted by the subtype_mark, or defined by the access_definition, after the reserved word return in the profile of the function. The expression, if any, of a return_statement is called the return_expression. The result subtype of a function is the subtype denoted by the subtype_mark after the reserved word return in the profile of the function. The expected type for the expression, if any, of a simple_return_statement is the result type of the corresponding function. The expected type for the expression of an extended_return_statement is that of the return_subtype_indication.

To be honest: The same applies to generic functions.

Legality Rules

A return_statement shall be within a callable construct, and it applies to the innermost callable_construct or extended_return_statement that contains it. A return_statement shall not be within a body that is within the construct to which the return_statement applies.

A function body shall contain at least one return_statement that applies to the function body, unless the function contains code_statements. A simple_return_statement shall include an expression—a return_expression if and only if it applies to a function body. An extended_return_statement with the reserved word constant shall include an expression.

Reason: The requirement that a function body has to have at least one return_statement is a “helpful” restriction. There has been some interest in lifting this restriction, or allowing a raise statement to substitute for the return_statement. However, there was enough interest in leaving it as is that we decided not to change it.

Ramification: A return_statement can apply to an extended_return_statement, so a simple_return_statement without an expression can be given in one. However, neither simple_return_statement with an expression nor an extended_return_statement can be given inside an extended_return_statement, as they must apply (directly) to a function body.

For an extended_return_statement that applies to a function body:

- If the result subtype of the function is defined by a subtype_mark, the return_subtype_indication shall be a subtype indication. The type of the subtype_indication shall be covered by the result_type of the function. If the result subtype of the function is constrained, then the subtype defined by the subtype_indication shall be statically compatible with the result subtype of the function; if the result type of the function is elementary, the two subtypes also be constrained and shall statically match this result subtype. If the result subtype of the function is indefinite, the subtype defined by the subtype_indication shall be a definite subtype, or there shall be an expression.

- If the result subtype of the function is defined by an access_definition, the return_subtype_indication shall be an access_definition. The subtype defined by the access_definition shall statically match the result subtype of the function. The accessibility level of this anonymous access subtype is that of the result subtype.

6.5 Return Statements 13 December 2012

5.4/3

- {AI05-0032-1} If the result subtype of the function is class-wide, the accessibility level of the type of the subtype defined by the return_subtype_indication shall not be statically deeper than that of the master that elaborated the function body.

5.6/3

- {AI95-00318-02} {AI05-0032-1} If the result subtype of the function is limited, then the expression of the return statement (if any) shall meet the restrictions described in 7.5 be an aggregate, a function call (or equivalent use of an operator), or a qualified_expression or parenthesized expression whose operand is one of these.

5.7/3

- {AI95-00416-01} {AI05-0032-1} {AI05-0051-1} If the result subtype of the function is class-wide, the accessibility level of the type of the expression (if any) of the return statement shall not be statically deeper than that of the master that elaborated the function body. If the result subtype has one or more unconstrained access discriminants, the accessibility level of the anonymous access type of each access discriminant, as determined by the expression of the simple_return_statement or the return_subtype_indication, shall not be statically deeper than that of the master that elaborated the function body.

5.8/3

- {AI05-0051-1} If the subtype determined by the expression of the simple_return_statement or by the return_subtype_indication has one or more access discriminants, the accessibility level of the anonymous access type of each access discriminant shall not be statically deeper than that of the master that elaborated the function body.

5.9/3

- {AI05-0277-1} If the keyword aliased is present in an extended_return_object_declaration, the type of the extended return object shall be immutably limited.

Static Semantics

5.10/3

{AI95-00318-02} {AI05-0015-1} {AI05-0144-2} Within an extended_return_statement, the return object is declared with the given defining_identifier, with the nominal subtype defined by the return_subtype_indication. An extended_return_statement with the reserved word constant is a full constant declaration that declares the return object to be a constant object.

Dynamic Semantics

5.11/3

{AI95-00318-02} {AI05-0015-1} {AI05-00416-01} {AI05-0032-1} For the execution of an extended_return_statement, the subtype_indication or access_definition is elaborated. This creates the nominal subtype of the return object. If there is an expression, it is evaluated and converted to the nominal subtype (which might raise Constraint_Error — see 4.6); the return object is created and the converted value is assigned to the return object. Otherwise, the return object is created and initialized by default as for a stand-alone object of its nominal subtype (see 3.3.1). If the nominal subtype is indefinite, the return object is constrained by its initial value. A check is made that the value of the return object belongs to the function result subtype. Constraint_Error is raised if this check fails.
If the result type is class-wide, then the tag of the result is the tag of the value of the expression. A check is made that the master accessibility level of the type identified by the tag of the result includes the elaboration is not deeper than that of the master that elaborated the function body. If this check fails, Program_Error is raised.

\{AI95-00318-02\} For the execution of a simple return_statement, the expression (if any) is first evaluated, and converted to the result subtype, and then is assigned to the anonymous return object.

**Ramification:** The conversion might raise Constraint_Error — (see 4.6).

\{AI95-00318-02\}  \{AI95-00416-01\}  \[If the return object has any parts that are tasks, the activation of those tasks does not occur until after the function returns (see 9.2).\] If the result type is class-wide, then the tag of the result is the tag of the value of the expression.

**Proof:** This is specified by the rules in 9.2.

Reason: Only the caller can know when task activations should take place, as it depends on the context of the call. If the function is being used to initialize the component of some larger object, then that entire object must be initialized before any task activations. Even after the outer object is fully initialized, task activations are still postponed until the begin at the end of the declarative part if the function is being used to initialize part of a declared object.

\{AI95-00318-02\}  \{AI95-00344-01\}  \{AI05-0024-1\}  \{AI05-0032-1\} If the result type of a function is a specific tagged type, the tag of the return object is that of the result type. If the result type is class-wide, the tag of the return object is that of the type of the subtype indication if it is specific, or otherwise that of the value of the expression. A check is made that the master accessibility level of the type identified by the tag of the result includes the elaboration is not deeper than that of the master that elaborated the function body. If this check fails, Program_Error is raised.

**Ramification:** \{AI95-00318-02\} The first sentence is true even if the tag of the expression is different, which could happen if the expression were a view conversion or a dereference of an access value. Note that for a limited type, because of the restriction to aggregates and function calls (and no conversions), the tag will already match.

Reason: \{AI95-00318-02\} The first rule ensures that a function whose result type is a specific tagged type always returns an object whose tag is that of the result type. This is important for dispatching on controlling result, and allows the caller to allocate the appropriate amount of space to hold the value being returned (assuming there are no discriminants). The master check prevents the returned object from outliving its type. Note that this check cannot fail for a specific tagged type, as the tag represents the function's type, which necessarily must be declared outside of the function. We can't use the normal accessibility level "deeper than" check here because we may have "incomparable" levels if the masters belong to two different tasks. This can happen when an accept statement calls a function declared in the enclosing task body, and the function returns an object passed to it from the accept statement, and this object was itself a parameter to the accept statement.

\{AI05-0073-1\} If the result subtype of the function is defined by an access_definition designating a specific tagged type T, a check is made that the result value is null or the tag of the object designated by the result value identifies T. Constraint_Error is raised if this check fails.

**Reason:** This check is needed so that dispatching on controlling access results works for tag-indeterminate functions. If it was not made, it would be possible for such functions to return an access to a descendant type, meaning the function could return an object with a tag different than the one assumed by the dispatching rules.

Paragraphs 9 through 20 were deleted.

\* \{AI95-00318-02\} If it is limited, then a check is made that the tag of the value of the return expression identifies the result type. Constraint_Error is raised if this check fails.
A type is a return-by-reference type if it is a descendant of one of the following:

- A tagged limited type;
- A task or protected type;
- A nonprivate type with the reserved word limited in its declaration;
- A composite type with a subcomponent of a return-by-reference type;
- A private type whose full type is a return-by-reference type.

Reason: These rules ensure that a function whose result type is a specific tagged type always returns an object whose tag is that of the result type. This is important for dispatching on controlling result, and, if nonlimited, allows the caller to allocate the appropriate amount of space to hold the value being returned (assuming there are no discriminants).

Discussion: This rule was unnecessarily confusing, and the parenthetical remark "(or a value with an associated object, see 6.2)" was added—and then the entire concept was deleted.

Discussion: Compare the definition of return-by-reference with that of by-reference. The return-by-reference types are all limited types except those that are limited only because of a limited private type with a nonlimited untagged full type.

Reason: This check can often be performed at compile time. It is defined to be a run-time check to avoid generic contract model problems. In a future version of the standard, we anticipate that function return of a local variable will be illegal for all limited types, eliminating the need for the run-time check except for dereferences of an access parameter.

Discussion: The above rules are such that there are no "Ada 83" types other than those containing tasks that are return by reference. This helps to minimize upward incompatibilities relating to return by reference.

Reason: This check can often be performed at compile time. It is defined to be a run-time check to avoid generic contract model problems. In a future version of the standard, we anticipate that function return of a local variable will be illegal for all limited types, eliminating the need for the run-time check except for dereferences of an access parameter.

Discussion: This check can often be performed at compile time. It is defined to be a run-time check to avoid generic contract model problems. In a future version of the standard, we anticipate that function return of a local variable will be illegal for all limited types, eliminating the need for the run-time check except for dereferences of an access parameter.

Discussion: Compare the definition of return-by-reference with that of by-reference. The return-by-reference types are all limited types except those that are limited only because of a limited private type with a nonlimited untagged full type.

Reason: This check can often be performed at compile time. It is defined to be a run-time check to avoid generic contract model problems. In a future version of the standard, we anticipate that function return of a local variable will be illegal for all limited types, eliminating the need for the run-time check except for dereferences of an access parameter.

Reason: This check can often be performed at compile time. It is defined to be a run-time check to avoid generic contract model problems. In a future version of the standard, we anticipate that function return of a local variable will be illegal for all limited types, eliminating the need for the run-time check except for dereferences of an access parameter.

Discussion: Compare the definition of return-by-reference with that of by-reference. The return-by-reference types are all limited types except those that are limited only because of a limited private type with a nonlimited untagged full type.

Reason: This check can often be performed at compile time. It is defined to be a run-time check to avoid generic contract model problems. In a future version of the standard, we anticipate that function return of a local variable will be illegal for all limited types, eliminating the need for the run-time check except for dereferences of an access parameter.
Implementation Note: \{AI05-0234-1\} The reason for saying “any part of the specific type” is to simplify implementation. In the case of class-wide result objects, this allows the testing of a simple flag in the tagged type descriptor that indicates whether the specific type has any parts with access discriminants. By basing the test on the type of the object rather than the object itself, we avoid concerns about whether subcomponents in variant parts and of arrays (which might be empty) are present.

Discussion: \{AI05-0234-1\} For a function with a class-wide result type, the access values that need to be checked are determined by the tag of the return object. In order to implement this accessibility check in the case where the tag of the result is not known statically at the point of the return statement, an implementation may need to somehow associate with the tag of a specific tagged type an indication of whether the type has unconstrained access discriminants (explicit or inherited) or has any subcomponents with such discriminants. If an implementation is already maintaining a statically initialized descriptor for some kind of each specific tagged type, then an additional Boolean could be added to this descriptor.

\{AI05-0005-1\} \{AI05-0234-1\} Note that the flag should only be queried in the case where the result object might have access discriminants that might have subtypes with "bad" accessibility levels (as determined by the rules of 3.10.2 for determining the accessibility level of the type of an access discriminant in the expression or return_subtype_indication of a return statement).

Thus, in a case like

\begin{verbatim}
type Global is access T'Class;
function F (Ptr : Global) return T'Class is
  begin
    return Ptr.all;
  end F;
\end{verbatim}

there is no need for a run-time accessibility check. While an object of T'Class "might have" access discriminants, the accessibility of those potential discriminants cannot be bad. The setting of the bit doesn't matter and there is no need to query it.

On the other hand, given

\begin{verbatim}
function F return T'Class is
  Local : T'Class := ... ;
  begin
    return Local;
  end F;
\end{verbatim}

In this case, a check would typically be required.

The need for including subcomponents in this check is illustrated by the following example:

\begin{verbatim}
X : aliased Integer;
type Component_Type (Discrim : access Integer := X'Access) is limited null record;
type Undiscriminated is record
  Fld : Component_Type;
end record;
function F return Undiscriminated is
  Local : aliased Integer;
  begin
    return X : Undiscriminated := (Fld => (Discrim => Local'Access)) do
        Foo;
        -- raises Program_Error after calling Foo,
    end return;
  end F;
\end{verbatim}

Ramification: \{AI05-0234-1\} In the case where the tag of the result is not known statically at the point of the return statement and the run-time accessibility check is needed, discriminant values and array bounds play no role in performing this check. That is, array components are assumed to have nonzero length and components declared within variant parts are assumed to be present. Thus, the check may be implemented simply by testing the aforementioned descriptor bit and conditionally raising Program_Error.

\{AI95-00318-02\} \{AI05-0058-1\} For the execution of an extended_return_statement, the handled_sequence of statements is executed. Within this handled_sequence of statements, the execution of a simple_return_statement that applies to the extended_return_statement causes a transfer of control that completes the extended_return_statement. Upon completion of a return statement that applies to a callable construct by the normal completion of a simple_return_statement or by reaching the end_return of an extended_return_statement Finally, a transfer of control is performed which completes the execution of the callable construct to which the return_statement applies, and returns to the caller.
Return Statements

Examples of return statements:

```
return;                         -- in a procedure body, entry_body,
accept_statement               -- accept_statement, or extended_return_statement, or
return Key_Value(Last_Index);   -- in a function body
```

{AI95-00318-02}  return  Node : Cell  do
                  -- in a function body, see 3.10.1 for Cell
              Node.Value := Result;
              Node.Succ := Next_Node;
          end return;

Incompatibilities With Ada 83

{AI95-00318-02}  In Ada 95, if the result type of a function has a part that is a task, then an attempt to return a local variable will raise Program_Error.  This is illegal in Ada 2005, see below.  In Ada 83, if a function returns a local variable containing a task, execution is erroneous according to AI83-00867.  However, there are other situations where functions that return tasks (or that return a variant record only one of whose variants includes a task) are correct in Ada 83 but will raise Program_Error according to the new rules.

The rule change was made because there will be more types (protected types, limited controlled types) in Ada 95 for which it will be meaningless to return a local variable, and making all of these erroneous is unacceptable.  The current rule was felt to be the simplest that kept upward incompatibilities to situations involving returning tasks, which are quite rare.

Wording Changes from Ada 83

{AI05-0299-1}  This subclause has been moved here from chapter 5, since it has mainly to do with subprograms.

A function now creates an anonymous object.  This is necessary so that controlled types will work.

{AI95-00318-02}  We have clarified that a return statement applies to a callable construct, not to a callable entity.

{AI95-00318-02}  There is no need to mention generics in the rules about where a return statement can appear and what it applies to; the phrase “body of a subprogram or generic subprogram” is syntactic, and refers exactly to “subprogram_body”.

Inconsistencies With Ada 95

{AI95-0416-1}  {AI05-0005-1}  {AI05-0050-1}  Added an Implementation Permission allowing early raising of Constraint_Error if the result cannot fit in the ultimate object.  This gives implementations more flexibility to do built-in-place returns, and is essential for limited types (which cannot be built in a temporary).  However, it allows raising an Constraint_Error in some cases where it would not be raised if the permission was not used.  See Inconsistencies With Ada 2005 for additional changes.  This case is potentially inconsistent with Ada 95, but a compiler does not have to take advantage of these permissions for any Ada 95 code, so there should be little practical impact.

Incompatibilities With Ada 95

{AI95-00318-02}  The entire business about return-by-reference types has been dropped.  Instead, the expression of a return statement of a limited type can only be an aggregate or function_call (see 7.5).  This means that returning a global object or type_conversion, legal in Ada 95, is now illegal.  Such functions can be converted to use anonymous access return types by adding access in the function definition and return statement, adding all in uses, and adding aliased in the object declarations.  This has the advantage of making the reference return semantics much clearer to the casual reader.

We changed these rules so that functions, combined with the new rules for limited types (7.5), can be used as build-in-place constructors for limited types.  This reduces the differences between limited and nonlimited types, which will make limited types useful in more circumstances.

Extensions to Ada 95

{AI95-00318-02}  The extended return statement is new.  This provides a name for the object being returned, which reduces the copying needed to return complex objects (including no copying at all for limited objects).  It also allows component-by-component construction of the return object.

Wording Changes from Ada 95

{AI95-00318-02}  The wording was updated to support anonymous access return subtypes.

{AI95-00318-02}  The term “return expression” was dropped because reviewers found it confusing when applied to the default expression of an extended return statement.

{AI95-00344-01}  {AI95-00416-01}  Added accessibility checks to class-wide return statements.  These checks could not fail in Ada 95 (as all of the types had to be declared at the same level, so the tagged type would necessarily have been at the same level as the type of the object).
Inconsistencies With Ada 2005

Correction: The Implementation Permission allowing early raising of Constraint_Error was modified to remove the most common of these cases from the permission (returning an object with mutable discriminants, where the return object is created with one set of discriminants and then changed to another). (The permission was also widened to allow the early check for constrained functions when that constraint is wrong.) However, there still is an unlikely case where the permission would allow an exception to be raised when none would be raised by the canonical semantics (when a return statement is abandoned). These changes can only remove the raising of an exception (or change the place where it is raised) compared to Ada 2005, so programs that depend on the previous behavior should be very rare.

Accessibility checks for access discriminants now depend on the master of the call rather than the point of declaration of the function. This will result in cases that used to raise Program_Error now running without raising any exception. This is technically inconsistent with Ada 2005 (as defined by Amendment 1), but it is unlikely that any real code depends on the raising of this exception.

Correction: Added a tag check for functions returning anonymous access-to-tagged types, so that dispatching of tag-indeterminate function works as expected. This is technically inconsistent with Ada 2005 (as defined by Amendment 1), but as the feature in question was newly added to Ada 2005, there should be little code that depends on the behavior that now raises an exception.

Incompatibilities With Ada 2005

Correction: The aliased keyword can now only appear on extended return objects with an immutably limited type. Other types would provide a way to get an aliased view of an object that is not necessarily aliased, which would be very bad. This is incompatible, but since the feature was added in Ada 2005, the keyword had no defined meaning in Ada 2005 (a significant oversight), and most sensible uses involve immutably limited types, it is unlikely that it appears meaningfully in existing programs.

Correction: Added wording to require static matching for unconstrained access types in extended return statements. This disallows adding or omitting null exclusions, and adding access constraints, in the declaration of the return object. While this is incompatible, the incompatible cases in question are either useless (access constraints – the constraint can be given on an allocator if necessary, and still must be given there even if given on the return object) or wrong (null exclusions – null could be returned from a function declared to be null excluding), so we expect them to be extremely rare in practice.

Extensions to Ada 2005

The return object of an extended return statement can be declared constant; this works similarly to a constant object declaration.

Added wording to allow the return_subtype_indication to have a specific type if the return subtype of the function is class-wide. Specifying the (specific) type of the return object is awkward without this change, and this is consistent with the way allocators work.

Wording Changes from Ada 2005

Correction: Corrected the master check for tags since the masters may be for different tasks and thus incomparable.

Correction: Corrected the wording defining returns for extended return statements, since leaving by an exit or goto is considered "normal" completion of the statement.

Correction: Added the extended_return_object_declaration to make other rules easier to write and eliminate the problem described in AI05-0205-1.

6.5.1 Nonreturning ProceduresPragma No_Return

Specifying aspectPragma No_Return to have the value True indicates that a procedure cannot return normally; it may propagate an exception or loop forever.

Discussion: AspectPragma No_Deposit will have to wait for Ada 20202012; :-)

6.5 Return Statements

13 December 2012  306
Paragraphs 2 and 3 were moved to Annex J, "Obsolescent Features".

Syntax

The form of a pragma No_Return, which is a representation pragma (see 13.1), is as follows:

```
pragma No_Return(procedure_local_name{, procedure_local_name});
```

Static Semantics

For a procedure or generic procedure, the following language-defined representation aspect may be specified:

No_Return

The type of aspect No_Return is Boolean. When aspect No_Return is True for an entity, the entity is said to be nonreturning.

If directly specified, the aspect_definition shall be a static expression. [This aspect is never inherited;] if not directly specified, the aspect is False.

Aspect Description for No_Return: A procedure will not return normally.

If a generic procedure is nonreturning, then so are its instances. If a procedure declared within a generic unit is nonreturning, then so are the corresponding copies of that procedure in instances.

Legality Rules

Aspect No_Return

Each procedure_local_name shall denote one or more procedures or generic procedures; the denoted entities are nonreturning. The procedure_local_name shall not be specified for denote a null procedure nor an instance of a generic unit.

Reason: A null procedure cannot have the appropriate nonreturning semantics, as it does not raise an exception or loop forever.

Ramification: The procedure can be abstract. The denoted declaration can be a renaming_declaration if it obeys the usual rules for representation pragmas; the renaming has to occur immediately within the same declarative region as the renamed subprogram. If a nonreturning procedure is renamed (anywhere) calls through the new name still have the nonreturning semantics.

A return statement shall not apply to a nonreturning procedure or generic procedure.

A procedure shall be nonreturning if it overrides a dispatching nonreturning procedure. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Reason: This ensures that dispatching calls to nonreturning procedures will, in fact, not return.

If a renaming-as-body completes a nonreturning procedure declaration, then the renamed procedure shall be nonreturning.

Reason: This ensures that no extra code is needed to implement the renames (that is, no wrapper is needed) as the body has the same property.

Paragraph 8 was deleted.

Static Semantics

If a generic procedure is nonreturning, then so are its instances. If a procedure declared within a generic unit is nonreturning, then so are the corresponding copies of that procedure in instances.
Dynamic Semantics

9.5.1 Nonreturning Procedures 13 December 2012 308

{AI95-00329-01} {AI95-00414-01} If the body of a nonreturning procedure completes normally, Program_Error is raised at the point of the call.

Discussion: Note that there is no name for suppressing this check, since the check represents a bug, imposes no time overhead, and minimal space overhead (since it can usually be statically eliminated as dead code).

Implementation Note: If a nonreturning procedure tries to return, we raise Program_Error. This is stated as happening at the call site, because we do not wish to allow the procedure to handle the exception (and then, perhaps, try to return again!). However, the expected run-time model is that the compiler will generate raise Program_Error at the end of the procedure body (but not handleable by the procedure itself), as opposed to doing it at the call site. (This is just like the typical run-time model for functions that fall off the end without returning a value). The reason is indirect calls: in P.all(...);, the compiler cannot know whether P designates a nonreturning procedure or a normal one. Putting the raise Program_Error in the procedure's generated code solves this problem neatly.

Similarly, if one passes a nonreturning procedure to a generic formal parameter, the compiler cannot know this at call sites (in shared code implementations), the raise-in-body solution deals with this neatly.

Examples

{AI95-00433-01} {AI05-0229-1}

procedure Fail(Msg : String);
-- raises Fatal_Error exception
withpragma No_Return(Fail);
-- Inform compiler and reader that procedure never returns normally

Extensions to Ada 95

10.a/2

{AI95-00329-01} {AI95-00414-01} Pragma No_Return is new.

Extensions to Ada 2005

10.b/3

{AI05-0229-1} Aspect No_Return is new; pragma No_Return is now obsolescent.

6.6 Overloading of Operators

An operator is a function whose designator is an operator_symbol. [Operators, like other functions, may be overloaded.]

Name Resolution Rules

2 Each use of a unary or binary operator is equivalent to a function_call with function_prefix being the corresponding operator_symbol, and with (respectively) one or two positional actual parameters being the operand(s) of the operator (in order).

2.a/3

To be honest: {AI05-0299-1} We also use the term operator (in ClauseSection 4 and in 6.1) to refer to one of the syntactic categories defined in 4.5, “Operators and Expression Evaluation” whose names end with “_operator:” logical_operator, relational_operator, binary_adding_operator, unary_adding_operator, multiplying_operator, and highest_precedence_operator.

2.b/3

Discussion: {AI05-0005-1} This equivalence extends to uses of function_call in most other language rules. However, as often happens, the equivalence is not perfect, as operator calls are not a name, while a function_call is a name. Thus, operator calls cannot be used in contexts that require a name (such as a rename of an object). A direct fix for this problem would be very disruptive, and thus we have not done that. However, qualifying an operator call can be used as a workaround in contexts that require a name.

Legality Rules

3/3

{AI05-0143-1} The subprogram_specification of a unary or binary operator shall have one or two parameters, respectively. The parameters shall be of mode in. A generic function instantiation whose designator is an operator_symbol is only allowed if the specification of the generic function has the corresponding number of parameters, and they are all of mode in.

4 Default_expressions are not allowed for the parameters of an operator (whether the operator is declared with an explicit subprogram_specification or by a generic_instantiation).
An explicit declaration of "/=" shall not have a result type of the predefined type Boolean.

Static Semantics

\{AI05-0128-1\} An explicit declaration of "+" whose result type is Boolean implicitly declares an operator declaration of "/=" that gives the complementary result.

Discussion: \{AI05-0128-1\} A "+=" defined by this rule is considered user-defined, which means that it will be inherited by a derived type. "User-defined" means "not language-defined" for the purposes of inheritance, that is anything other than predefined operators.

NOTE
9 The operators "+" and "−" are both unary and binary operators, and hence may be overloaded with both one- and two-parameter functions.

Examples of user-defined operators:

function "+" (Left, Right : Matrix) return Matrix;
function "+" (Left, Right : Vector) return Vector;

-- assuming that A, B, and C are of the type Vector
-- the following two statements are equivalent:
A := B + C;
A := "+"(B, C);

Examples

Extensions to Ada 83

Explicit declarations of "+" are now permitted for any combination of parameter and result types.

Explicit declarations of "/=" are now permitted, so long as the result type is not Boolean.

Wording Changes from Ada 2005

\{AI05-0128-1\} Correction: Corrected the wording so that only explicit declarations of "+" cause an implicit declaration of "/="; otherwise, we could get multiple implicit definitions of "/=" without an obvious way to chose between them.

\{AI05-0143-1\} Added wording so that operators only allow parameters of mode in. This was made necessary by the elimination elsewhere of the restriction that function parameters be only of mode in.

6.7 Null Procedures

\{AI95-00348-01\} A null Procedure declaration provides a shorthand to declare a procedure with an empty body.

Syntax

\{AI95-00348-01\} \{AI05-0183-1\} null Procedure declaration ::= [overriding_indicator] procedure specification is null [aspect specification];

Legality Rules

\{AI05-0177-1\} If a null Procedure declaration is a completion, it shall be the completion of a subprogram declaration or generic subprogram declaration. The profile of a null Procedure declaration that completes a declaration shall conform fully to that of the declaration.
Static Semantics

A null procedure declaration declares a null procedure. A completion is not allowed for a null procedure declaration; however, a null procedure declaration can complete a previous declaration.

Reason: There are no null functions because the return value has to be constructed somehow; a function that always raises Program_Error doesn't seem very useful or worth the complication.

Dynamic Semantics

The execution of a null procedure is invoked by a subprogram call. For the execution of a subprogram call on a null procedure, the execution of the subprogram_body has no effect.

Ramification: Thus, a null procedure is equivalent to the body

\begin{verbatim}
begin
  null;
end;
\end{verbatim}

with the exception that a null procedure can be used in place of a procedure specification.

The elaboration of a null procedure declaration has no other effect than to establish that the null procedure can be called without failing the Elaboration_Check.

Examples

procedure Simplify(Expr : in out Expression) is null; -- see 3.9
-- By default, Simplify does nothing, but it may be overridden in extensions of Expression

Extensions to Ada 95

Null procedures are new.

Extensions to Ada 2005

A null procedure declaration can now be a completion.

An optional aspect_specification can be used in a null procedure declaration. This is described in 13.1.1.

6.8 Expression Functions

An expression function declaration provides a shorthand to declare a function whose body consists of a single return statement.

Syntax

expression_function_declaration ::= [overriding_indicator] function_specification is (expression) [aspect_specification];

Name Resolution Rules

The expected type for the expression of an expression function declaration is the result type (see 6.5) of the function.

Legality Rules

If an expression function declaration is a completion, it shall be the completion of a subprogram_declaration or generic_subprogram_declaration. The profile of an expression function_declaration that completes a declaration shall conform fully to that of the declaration.
If the result subtype has one or more unconstrained access discriminants, the accessibility level of the anonymous access type of each access discriminant, as determined by the expression of the expression function, shall not be statically deeper than that of the master that elaborated the expression-function_declaration.

Ramification: This can only fail if the discriminant is an access to a part of a non-aliased parameter, as there can be no local declarations here.

Discussion: We don't need to repeat any of the other Legality Rules for return statements since none of them can fail here: the implicit return statement has to apply to this function (and isn't nested in something), there clearly is a return statement in this function, and the static classwide accessibility check cannot fail as a tagged type cannot be declared locally in an expression function.

Static Semantics

An expression-function_declaration declares an expression function. A completion is not allowed for an expression-function_declaration; however, an expression-function-declaration can complete a previous declaration.

Dynamic Semantics

The execution of an expression function is invoked by a subprogram call. For the execution of a subprogram call on an expression function, the execution of the subprogram_body executes an implicit function body containing only a simple_return_statement whose expression is that of the expression function.

Discussion: The last sentence effectively means that all of the dynamic wording in 6.5 applies as needed, and we don't have to repeat it here.

The elaboration of an expression-function_declaration has no other effect than to establish that the expression function can be called without failing the Elaboration_Check.

Examples

function Is_Origin (P : in Point) return Boolean is -- see 3.9 (P.X = 0.0 and P.Y = 0.0);

Extensions to Ada 2005

Expression functions are new in Ada 2012.
7 Packages

[Packages are program units that allow the specification of groups of logically related entities. Typically, a package contains the declaration of a type (often a private type or private extension) along with the declarations of primitive subprograms of the type, which can be called from outside the package, while their inner workings remain hidden from outside users.]

7.1 Package Specifications and Declarations

[A package is generally provided in two parts: a package_specification and a package_body. Every package has a package_specification, but not all packages have a package_body.]

Syntax

```
package_declaration ::= package_specification;

{AI05-0183-1} package_specification ::= package defining_program_unit_name
                                    [aspect_specification] is
                                    {basic_declarative_item}
                                    [private
                                    {basic_declarative_item}]
                                    end [{parent_unit_name.identifier}
If an identifier or parent_unit_name.identifier appears at the end of a package_specification, then this sequence of lexical elements shall repeat the defining_program_unit_name.

Legality Rules

{AI95-00434-01} A package_declaration or generic_package_declaration requires a completion [(a body)] if it contains any basic_declarative_item[declarative_item] that requires a completion, but whose completion is not in its package_specification.

To be honest: {AI05-0229-1} If an implementation supports it, a pragma Import may substitute for the body of a package or generic package may be imported (using aspect Import, see B.1), in which case no explicit body is allowed.

Static Semantics

{AI95-00420-01} {AI95-00434-01} The first list of basic_declarative_item[declarative_item] of a package_specification of a package other than a generic formal package is called the visible part of the package. [The optional list of basic_declarative_item[declarative_item] after the reserved word private (of any package_specification) is called the private part of the package. If the reserved word private does not appear, the package has an implicit empty private part.] Each list of basic_declarative_item of a package_specification forms a declaration list of the package.

Ramification: This definition of visible part does not apply to generic formal packages — 12.7 defines the visible part of a generic formal package.

The implicit empty private part is important because certain implicit declarations occur there if the package is a child package, and it defines types in its visible part that are derived from, or contain as components, private types declared within the parent package. These implicit declarations are visible in children of the child package. See 10.1.1.

[An entity declared in the private part of a package is visible only within the declarative region of the package itself (including any child units — see 10.1.1). In contrast, expanded names denoting entities declared in the visible part can be used even outside the package; furthermore, direct visibility of such entities can be achieved by means of use_clauses (see 4.1.3 and 8.4).]
7.1 Package Specifications and Declarations

Dynamic Semantics

The elaboration of a package_declaration consists of the elaboration of its basic_declarative_items in the given order.

NOTES

1. The visible part of a package contains all the information that another program unit is able to know about the package.

2. If a declaration occurs immediately within the specification of a package, and the declaration has a corresponding completion that is a body, then that body has to occur immediately within the body of the package.

Proof: This follows from the fact that the declaration and completion are required to occur immediately within the same declarative region, and the fact that bodies are disallowed (by the Syntax Rules) in package_specifications. This does not apply to instances of generic units, whose bodies can occur in package_specifications.

Examples

Example of a package declaration:

package Rational_Numbers is
  type Rational is record
    Numerator   : Integer;
    Denominator : Positive;
  end record;

  function "="(X,Y : Rational) return Boolean;
  function "/"  (X,Y : Integer) return Rational; -- to construct a rational number
  function "+"  (X,Y : Rational) return Rational;
  function "-"  (X,Y : Rational) return Rational;
  function "+"  (X,Y : Rational) return Rational;
  function "/"  (X,Y : Rational) return Rational;
end Rational_Numbers;

There are also many examples of package declarations in the predefined language environment (see Annex A).

Incompatibilities With Ada 83

In Ada 83, a library package is allowed to have a body even if it doesn't need one. In Ada 95, a library package body is either required or forbidden — never optional. The workaround is to add pragma Elaborate_Body, or something else requiring a body, to each library package that has a body that isn't otherwise required.

Wording Changes from Ada 83

{AI05-0299-1} We have moved the syntax into this subclause and the next subclause from RM83-7.1, “Package Structure”, which we have removed.

RM83 was unclear on the rules about when a package requires a body. For example, RM83-7.1(4) and RM83-7.1(8) clearly forgot about the case of an incomplete type declared in a package_declaration but completed in the body. In addition, RM83 forgot to make this rule apply to a generic package. We have corrected these rules. Finally, since we now allow a pragma Import for any explicit declaration, the completion rules need to take this into account as well.

Wording Changes from Ada 95

{AI95-00420-01} Defined “declaration list” to avoid ambiguity in other rules as to whether packages are included.

Extensions to Ada 2005

{AI05-0183-1} An optional aspect_specification can be used in a package_specification. This is described in 13.1.1.

7.2 Package Bodies

In contrast to the entities declared in the visible part of a package, the entities declared in the package_body are visible only within the package_body itself. As a consequence, a package with a
package_body can be used for the construction of a group of related subprograms in which the logical operations available to clients are clearly isolated from the internal entities.]

Syntax

\{AI05-0267-1\} package_body ::=  
  package_body defining_program_unit_name  
  [aspect_specification] is  
  declarative_part  
  [begin  
    handled_sequence_of_statements]  
  end [[parent_unit_name.]identifier];

If an identifier or parent_unit_name.identifier appears at the end of a package_body, then this sequence of lexical elements shall repeat the defining_program_unit_name.

Legality Rules

A package_body shall be the completion of a previous package_declaration or generic_package_declaration. A library package_declaration or library generic_package_declaration shall not have a body unless it requires a body[; pragma Elaborate_Body can be used to require a library_unit_declaration to have a body (see 10.2.1) if it would not otherwise require one].

Ramification: The first part of the rule forbids a package_body from standing alone — it has to belong to some previous package_declaration or generic_package_declaration.

A nonlibrary package_declaration or nonlibrary generic_package_declaration that does not require a completion may have a corresponding body anyway.

Static Semantics

\{AI05-0299-1\} In any package_body without statements there is an implicit null_statement. For any package_declaration without an explicit completion, there is an implicit package_body containing a single null_statement. For a noninstance, nonlibrary package, this body occurs at the end of the declarative_part of the innermost enclosing program unit or block_statement; if there are several such packages, the order of the implicit package_bodies is unspecified. [(For an instance, the implicit package_body occurs at the place of the instantiation (see 12.3). For a library package, the place is partially determined by the elaboration dependences (see ClauseSection 10.).)]

Discussion: Thus, for example, we can refer to something happening just after the begin of a package_body, and we can refer to the handled_sequence_of_statements of a package_body, without worrying about all the optional pieces. The place of the implicit body makes a difference for tasks activated by the package. See also RM83-9.3(5).

The implicit body would be illegal if explicit in the case of a library package that does not require (and therefore does not allow) a body. This is a bit strange, but not harmful.

Dynamic Semantics

For the elaboration of a nongeneric package_body, its declarative_part is first elaborated, and its handled_sequence_of_statements is then executed.

NOTES

3 A variable declared in the body of a package is only visible within this body and, consequently, its value can only be changed within the package_body. In the absence of local tasks, the value of such a variable remains unchanged between calls issued from outside the package to subprograms declared in the visible part. The properties of such a variable are similar to those of a “static” variable of C.

4 The elaboration of the body of a subprogram explicitly declared in the visible part of a package is caused by the elaboration of the body of the package. Hence a call of such a subprogram by an outside program unit raises the exception Program_Error if the call takes place before the elaboration of the package_body (see 3.11).
Examples

Example of a package body (see 7.1):

```ada
package body Rational_Numbers is
    procedure Same_Denominator (X, Y : in out Rational) is
        begin
            -- reduces X and Y to the same denominator:
            ...
        end Same_Denominator;

    function "=" (X, Y : Rational) return Boolean is
        U : Rational := X;
        V : Rational := Y;
        begin
            Same_Denominator (U, V);
            return U.Numerator = V.Numerator;
        end "=";

    function "/" (X, Y : Integer) return Rational is
        begin
            if Y > 0 then
                return (Numerator => X, Denominator => Y);
            else
                return (Numerator => -X, Denominator => -Y);
            end if;
        end "/";

    function "+" (X, Y : Rational) return Rational is ...
    function "-" (X, Y : Rational) return Rational is ...
    function "%" (X, Y : Rational) return Rational is ...
    function "/" (X, Y : Rational) return Rational is ...
end Rational_Numbers;
```

Wording Changes from Ada 83

15.a The syntax rule for package_body now uses the syntactic category handled_sequence_of_statements.
15.b The declarative_part of a package_body is now required; that doesn't make any real difference, since a declarative_part can be empty.
15.c RM83 seems to have forgotten to say that a package_body can't stand alone, without a previous declaration. We state that rule here.
15.d RM83 forgot to restrict the definition of elaboration of package_bodies to nongeneric ones. We have corrected that omission.
15.e The rule about implicit bodies (from RM83-9.3(5)) is moved here, since it is more generally applicable.

Extensions to Ada 2005

[A105-0267-1] An optional aspect_specification can be used in a package_body. This is described in 13.1.1.

7.3 Private Types and Private Extensions

[The declaration (in the visible part of a package) of a type as a private type or private extension serves to separate the characteristics that can be used directly by outside program units (that is, the logical properties) from other characteristics whose direct use is confined to the package (the details of the definition of the type itself). See 3.9.1 for an overview of type extensions.]

Language Design Principles

1.a A private (untagged) type can be thought of as a record type with the type of its single (hidden) component being the full view.
1.b A private tagged type can be thought of as a private extension of an anonymous parent with no components. The only dispatching operation of the parent is equality (although the Size attribute, and, if nonlimited, assignment are allowed, and those will presumably be implemented in terms of dispatching).
Syntax

private_type_declaration ::= type defining_identifier [discriminant_part] is [abstract] [tagged] [limited] private [aspect_specification];

private_extension_declaration ::= type defining_identifier [discriminant_part] is [abstract] [limited] [synchronized] new ancestor_subtype_indication [and interface_list] with private [aspect_specification];

Legality Rules

A private_type_declaration or private_extension_declaration declares a partial view of the type; such a declaration is allowed only as a declarative_item of the visible part of a package, and it requires a completion, which shall be a full_type_declaration that occurs as a declarative_item of the private part of the package. [The view of the type declared by the full_type_declaration is called the full view.] A generic formal private type or a generic formal private extension is also a partial view.

To be honest: A private type can also be imported (using aspect Import, see B.1), in which case no completion is allowed completed by a pragma Import, if supported by an implementation.

Reason: We originally used the term “private view,” but this was easily confused with the view provided from the private part, namely the full view.

Proof: \{AI95-00326-01\} Full view is now defined in 3.2.1, “Type Declarations”, as all types now have them.

[A type shall be completely defined before it is frozen (see 3.11.1 and 13.14). Thus, neither the declaration of a variable of a partial view of a type, nor the creation by an allocator of an object of the partial view are allowed before the full declaration of the type. Similarly, before the full declaration, the name of the partial view cannot be used in a generic_instantiation or in a representation item.]

Proof: This rule is stated officially in 3.11.1, “Completions of Declarations”.

\{AI95-00419-01\} \{AI95-00443-01\} [A private type is limited if its declaration includes the reserved word limited; a private extension is limited if its ancestor type is a limited type that is not an interface type, or if the reserved word limited or synchronized appears in its definition.] If the partial view is nonlimited, then the full view shall be nonlimited. If a tagged partial view is limited, then the full view shall be limited. [On the other hand, if an untagged partial view is limited, the full view may be limited or nonlimited.]

If the partial view is tagged, then the full view shall be tagged. [On the other hand, if the partial view is untagged, then the full view may be tagged or untagged.] In the case where the partial view is untagged and the full view is tagged, no derivatives of the partial view are allowed within the immediate scope of the partial view; [derivatives of the full view are allowed.]

Ramification: Note that deriving from a partial view within its immediate scope can only occur in a package that is a child of the one where the partial view is declared. The rule implies that in the visible part of a public child package, it is impossible to derive from an untagged private type declared in the visible part of the parent package in the case where the full view of the parent type turns out to be tagged. We considered a model in which the derived type was implicitly redeclared at the earliest place within its immediate scope where characteristics needed to be added. However, we rejected that model, because (1) it would imply that (for an untagged type) subprograms explicitly declared after the derived type could be inherited, and (2) to make this model work for composite types as well, several implicit redeclarations would be needed, since new characteristics can become visible one by one; that seemed like too much mechanism.

Discussion: The rule for tagged partial views is redundant for partial views that are private extensions, since all extensions of a given ancestor tagged type are tagged, and limited if the ancestor is limited. We phrase this rule partially redundantly to keep its structure parallel with the other rules.
To be honest: This rule is checked in a generic unit, rather than using the “assume the best” or “assume the worst” method.

Reason: \{AI95-00230-01\} Tagged limited private types have certain capabilities that are incompatible with having assignment for the full view of the type. In particular, tagged limited private types can be extended with access discriminants and components of a limited type, which works only because assignment is not allowed. Consider the following example:

```ada
package P1 is
  type T1 is tagged limited private;
  procedure Foo(X : in T1'Class);
private
  type T1 is tagged null record; -- Illegal!
  -- This should say "tagged limited null record".
end P1;

package body P1 is
  type A is access T1'Class;
  Global : A;
  procedure Foo(X : in T1'Class) is
  begin
    Global := new T1'Class'(X);
    -- This would be illegal if the full view of
    -- T1 were limited, like it's supposed to be.
  end Foo;
end P1;

package P2 is
  type T2(D : access Integer) -- Trouble!
    is new P1.T1 with
  record
    My_Task : Some_Task_Type; -- TroubleMore trouble!
  end record;
end P2;

with P1;
with P2;
procedure Main is
  Local : aliased Integer;
  Y : P2.T2(D => Local'Access);
begin
  P1.Foo(Y);
end Main;
```

This rule is not needed for private extensions, because they inherit their limitedness from their ancestor, and there is a separate rule forbidding limited components of the corresponding record extension if the parent is nonlimited.

Ramification: A type derived from an untagged private type is untagged, even if the full view of the parent is tagged, and even at places that can see the parent:

```ada
package P is
  type Parent is private;
private
  type Parent is tagged record
    X: Integer;
  end record;
end P;

package Q is
  type T is new P.Parent;
end Q;

with Q; use Q;
package body P is
  ... T'Class ... -- Illegal!
  Object: T;
  ... Object.X ... -- Illegal!
  ... Parent(Object).X ... -- OK.
end P;
```
The declaration of T declares an untagged view. This view is always untagged, so T'Class is illegal, it would be illegal to extend T, and so forth. The component name X is never visible for this view, although the component is still there — one can get one's hands on it via a type_conversion.

{AI95-00396-01} If a full type has a partial view that is tagged, then:
- the partial view shall be a synchronized tagged type (see 3.9.4) if and only if the full type is a synchronized tagged type;
  - Reason: Since we do not allow record extensions of synchronized tagged types, this property has to be visible in the partial view to avoid privacy breaking. Generic formals do not need a similar rule as any extensions are rechecked for legality in the specification, and extensions of tagged formals are always illegal in a generic body.
- the partial view shall be a descendant of an interface type (see 3.9.4) if and only if the full type is a descendant of the interface type.
  - Reason: Consider the following example:

```ada
package P is
  package Pkg is
    type Ifc is interface;
    procedure Foo (X : Ifc) is abstract;
  end Pkg;
  type Parent_1 is tagged null record;
  type T1 is new Parent_1 with private;
  private
    type Parent_2 is new Parent_1 and Pkg.Ifc with null record;
    procedure Foo (X : Parent_2); -- Foo #1
    type T1 is new Parent_2 with null record; -- Illegal.
  end P;
  with P;
  package P_Client is
    type T2 is new T1 and P.Pkg.Ifc with null record;
    procedure Foo (X : T2); -- Foo #2
    X : T2;
  end P_Client;
  with P_Client;
package body P is
  ...;
  procedure Bar (X : T1'Class) is
    begin
      Pkg.Foo (X); -- should call Foo #1 or an override thereof
    end;
begin
  Pkg.Foo (Pkg.Ifc'Class (P_Client.X)); -- should call Foo #2
  Bar (T1'Class (P_Client.X));
  end P;
end P;
```

This example is illegal because the completion of T1 is descended from an interface that the partial view is not descended from. If it were legal, T2 would implement Ifc twice, once in the visible part of P, and once in the visible part of P_Client. We would need to decide how Foo #1 and Foo #2 relate to each other. There are two options: either Foo #2 overrides Foo #1, or it doesn't.

If Foo #2 overrides Foo #1, we have a problem because the client redefines a behavior that it doesn't know about, and we try to avoid this at all costs, as it would lead to a breakdown of whatever abstraction was implemented. If the abstraction didn't expose that it implements Ifc, there must be a reason, and it should be able to depend on the fact that no overriding takes place in clients. Also, during maintenance, things may change and the full view might implement a different set of interfaces. Furthermore, the situation is even worse if the full type implements another interface Ifc2 that happens to have a conforming Foo (otherwise unrelated, except for its name and profile).

If Foo #2 doesn't override Foo #1, there is some similarity with the case of normal tagged private types, where a client can declare an operation that happens to conform to some private operation, and that's OK, it gets a different slot in the type descriptor. The problem here is that T2 would implement Ifc in two different ways, and through conversions to Ifc'Class we could end up with visibility on both of these two different implementations. This is the "diamond inheritance" problem of C++ all over again, and we would need some kind of a preference rule to pick one implementation. We don't want to go there (if we did, we might as well provide full-fledged multiple inheritance).

Note that there wouldn't be any difficulty to implement the first option, so the restriction is essentially methodological. The second option might be harder to implement, depending on the language rules that we would choose.
The ancestor subtype of a private_extension_declaration is the subtype defined by the ancestor_subtype_indication; the ancestor type shall be a specific tagged type. The full view of a private extension shall be derived (directly or indirectly) from the ancestor type. In addition to the places where Legality Rules normally apply (see 12.3), the requirement that the ancestor be specific applies also in the private part of an instance of a generic unit.

Reason: This rule allows the full view to be defined through several intermediate derivations, possibly from a series of types produced by generic_instantiations.

8.a

If the reserved word limited appears in a private_extension_declaration, the ancestor type shall be a limited type. If the reserved word synchronized appears in a private_extension_declaration, the ancestor type shall be a limited interface.

8.1/2

If the declaration of a partial view includes a known_discriminant_part, then the full_type_declaration shall have a fully conforming [(explicit)] known_discriminant_part [(see 6.3.1, “Conformance Rules”).]

Discussion: If the ancestor subtype has discriminants, then it is usually best to make it unconstrained.

That is, the following is illegal:

```ada
package P is
type T(D : Integer) is private;
private type T is new Some_Other_Type; -- Illegal!
end P;
```

even if Some_Other_Type has an integer discriminant called D.

Reason: The first part ensures that the full view has the same discriminants as the partial view. The second part ensures that if the partial view is unconstrained, then the full view is also unconstrained; otherwise, a client might constrain the partial view in a way that conflicts with the constraint on the full view.

If a private extension inherits known discriminants from the ancestor subtype, then the full view shall also inherit its discriminants from the ancestor subtype, and the parent subtype of the full view shall be constrained if and only if the ancestor subtype is constrained.

Reason: The first part ensures that the full view has the same discriminants as the partial view. The second part ensures that if the partial view is unconstrained, then the full view is also unconstrained; otherwise, a client might constrain the partial view in a way that conflicts with the constraint on the full view.

If a partial view has unknown discriminants, then the full_type_declaration may define a definite or an indefinite subtype, with or without discriminants.

If a partial view has neither known nor unknown discriminants, then the full_type_declaration shall define a definite subtype.
If the ancestor subtype of a private extension has constrained discriminants, then the parent subtype of the full view shall impose a statically matching constraint on those discriminants.

**Ramification:** If the parent type of the full view is not the ancestor type, but is rather some descendant thereof, the constraint on the discriminants of the parent type might come from the declaration of some intermediate type in the derivation chain between the ancestor type and the parent type.

**Reason:** This prevents the following:

```ada
package P is
  type T2 is new T1(Discrim => 3) with private;
private
  type T2 is new T1(Discrim => 999) -- Illegal!
  with record ...;
end P;
```

The constraints in this example do not statically match.

If the constraint on the parent subtype of the full view depends on discriminants of the full view, then the ancestor subtype has to be unconstrained:

```ada
package P is
  type One_Discrims(A: Integer) is tagged ...;
  ...
  package P is
    type Two_Discrims(B: Boolean; C: Integer) is new One_Discrims with private;
  private
    type Two_Discrims(B: Boolean; C: Integer) is new One_Discrims(A => C) with record ...;
  end P;
end record;
end P;
```

The above example would be illegal if the private extension said “is new One_Discrims(A => C);”, because then the constraints would not statically match. (Constraints that depend on discriminants are not static.)

**Static Semantics**

A `private_type_declaration` declares a private type and its first subtype. Similarly, a `private_extension_declaration` declares a private extension and its first subtype.

**Discussion:** A `package-private type` is one declared by a `private_type_declaration`; that is, a private type other than a generic formal private type. Similarly, a `package-private extension` is one declared by a `private_extension_declaration`. These terms are not used in the RM95 version of this document.

{AI05-0269-1} A declaration of a partial view and the corresponding `full_type_declaration` define two views of a single type. The declaration of a partial view together with the visible part define the operations that are available to outside program units; the declaration of the full view together with the private part define other operations whose direct use is possible only within the declarative region of the package itself. Moreover, within the scope of the declaration of the full view, the `characteristics` (see 3.4) of the type are determined by the full view; in particular, within its scope, the full view determines the classes that include the type, which components, entries, and protected subprograms are visible, what attributes and other predefined operations are allowed, and whether the first subtype is static. See 7.3.1.

{AI95-00401-01} {AI05-0110-1} For a private extension, the `characteristics` (including components, but excluding discriminants if unless there is a new discriminant_part specified), predefined operators, and inherited user-defined primitive subprograms are determined by its ancestor type and its progenitor types (if any), in the same way that those of a record extension are determined by those of its progenitor types and user-defined primitive subprograms from its parent type and its progenitor types (see 3.4 and 7.3.1).

**To be honest:** {AI05-0110-1} If an operation of the ancestor or parent type is abstract, then the abstractness of the inherited operation is different for nonabstract record extensions than for nonabstract private extensions (see 3.9.3).
The elaboration of a private type declaration creates a partial view of a type. The elaboration of a private extension declaration elaborates the ancestor subtype indication, and creates a partial view of a type.

NOTES
5. The partial view of a type as declared by a private type declaration is defined to be a composite view (in 3.2). The full view of the type might or might not be composite. A private extension is also composite, as is its full view.

6. [AI95-00318-02] Declaring a private type with an unknown discriminant part is a way of preventing clients from creating uninitialized objects of the type; they are then forced to initialize each object by calling some operation declared in the visible part of the package. If such a type is also limited, then no objects of the type can be declared outside the scope of the full type declaration, restricting all object creation to the package defining the type. This allows complete control over all storage allocation for the type. Objects of such a type can still be passed as parameters, however.

Discussion: Packages with private types are analogous to generic packages with formal private types, as follows: The declaration of a package-private type is like the declaration of a formal private type. The visible part of the package is like the generic formal part; these both specify a contract (that is, a set of operations and other things available for the private type). The private part of the package is like an instantiation of the generic; they both give a full type declaration that specifies implementation details of the private type. The clients of the package are like the body of the generic; usage of the private type in these places is restricted to the operations defined by the contract.

In other words, being inside the package is like being outside the generic, and being outside the package is like being inside the generic; a generic is like an “inside-out” package.

This analogy also works for private extensions in the same inside-out way.

Many of the legality rules are defined with this analogy in mind. See, for example, the rules relating to operations of [formal] derived types.

The completion rules for a private type are intentionally quite similar to the matching rules for a generic formal private type.

This analogy breaks down in one respect: a generic actual subtype is a subtype, whereas the full view for a private type is always a new type. (We considered allowing the completion of a private type declaration to be a subtype declaration, but the semantics just won’t work.) This difference is behind the fact that a generic actual type can be class-wide, whereas the completion of a private type always declares a specific type.

7. [AI95-00401] The ancestor type specified in a private extension declaration and the parent type specified in the corresponding declaration of a record extension given in the private part need not be the same. If the ancestor type is not an interface type, the parent type of the full view can be any descendant of the ancestor type. In this case, for a primitive subprogram that is inherited from the ancestor type and not overridden, the formal parameter names and default expressions (if any) come from the corresponding primitive subprogram of the specified ancestor type, while the body comes from the corresponding primitive subprogram of the parent type of the full view. See 3.9.2.

8. [AI95-00401] If the ancestor type specified in a private extension declaration is an interface type, the parent type can be any type so long as the full view is a descendant of the ancestor type. The progenitor types specified in a private extension declaration and the progenitor types specified in the corresponding declaration of a record extension given in the private part need not be the same — the only requirement is that the private extension and the record extension be descended from the same set of interfaces.

Examples

type Key is private;
type FileName is limited private;

Example of a private extension declaration:

type List is new Ada.Finalization.Controlled with private;

Extensions to Ada 83

In Ada 83, a private type without discriminants cannot be completed with a type with discriminants. Ada 95 allows the full view to have discriminants, so long as they have defaults (that is, so long as the first subtype is definite). This change is made for uniformity with generics, and because the rule as stated is simpler and easier to remember than the Ada 83 rule. In the original version of Ada 83, the same restriction applied to generic formal private types. However,
the restriction was removed by the ARG for generics. In order to maintain the “generic contract/private type contract analogy” discussed above, we have to apply the same rule to package-private types. Note that a private untagged type without discriminants can be completed with a tagged type with discriminants only if the full view is constrained, because discriminants of tagged types cannot have defaults.

**Wording Changes from Ada 83**

RM83-7.4.1(4), “Within the specification of the package that declares a private type and before the end of the corresponding full type declaration, a restriction applies...”, is subsumed (and corrected) by the rule that a type shall be completely defined before it is frozen, and the rule that the parent type of a derived type declaration shall be completely defined, unless the derived type is a private extension.

**Extensions to Ada 95**

{AI95-00251-01} {AI95-00396-01} {AI95-00401-01} Added interface list to private extensions to support interfaces and multiple inheritance (see 3.9.4).

{AI95-00419-01} A private extension may specify that it is a limited type. This is required for interface ancestors (from which limitedness is not inherited), but it is generally useful as documentation of limitedness.

{AI95-00443-01} A private extension may specify that it is a synchronized type. This is required in order so that a regular limited interface can be used as the ancestor of a synchronized type (we do not allow hiding of synchronization).

**Extensions to Ada 2005**

{AI05-0183-1} An optional aspect_specification can be used in a private_type_declaration and a private_extension_declaration. This is described in 13.1.1.

**Wording Changes from Ada 2005**

{AI05-0110-1} **Correction:** The description of how a private extension inherits characteristics was made consistent with the way formal derived types inherit characteristics (see 12.5.1).

### 7.3.1 Private Operations

For a type declared in the visible part of a package or generic package, certain operations on the type do not become visible until later in the package — either in the private part or the body. Such *private operations* are available only inside the declarative region of the package or generic package.

**Static Semantics**

The predefined operators that exist for a given type are determined by the classes to which the type belongs. For example, an integer type has a predefined "+" operator. In most cases, the predefined operators of a type are declared immediately after the definition of the type; the exceptions are explained below. Inherited subprograms are also implicitly declared immediately after the definition of the type, except as stated below.

{8652/0019} {AI95-00033-01} {AI05-0029-1} For a composite type, the characteristics (see 7.3) of the type are determined in part by the characteristics of its component types. At the place where the composite type is declared, the only characteristics of component types used are those characteristics visible at that place. If later immediately within the declarative region in which the composite type is declared, additional characteristics become visible for a component type, then any corresponding characteristics become visible for the composite type. Any additional predefined operators are implicitly declared at that place. If there is no such place, then additional predefined operators are not declared at all, but they still exist.

**Reason:** {AI05-0029-1} We say that the predefined operators exist because they can emerge in some unusual generic instantiations. See 12.5.

**Discussion:** {AI05-0029-1} The predefined operators for the underlying class of a type always exist, even if there is no visibility on that underlying class. This rule is simply about where (if ever) those operators are declared (and thus become usable). The “additional predefined operators” defined by this rule are any that are not declared at the point of
the original type declaration. For instance, a type derived from a private type whose full type is type String always will have a "=" operator, but where that operator is declared (and thus whether it is visible) will depend on the visibility of the full type of the parent type.

{8652/0019} {AI95-00033-01} The corresponding rule applies to a type defined by a derived_type_definition, if there is a place immediately within the declarative region in which the type is declared within its immediate scope where additional characteristics of its parent type become visible.

{8652/0019} {AI95-00033-01} [For example, an array type whose component type is limited private becomes nonlimited if the full view of the component type is nonlimited and visible at some later place immediately within the declarative region in which the array type is declared within the immediate scope of the array type. In such a case, the predefined "=" operator is implicitly declared at that place, and assignment is allowed after that place.]

{AI05-0115-1} {AI05-0269-1} A type is a descendant of the full view of some ancestor of its parent type only if the current view it has of its parent is a descendant of the full view of that ancestor. More generally, at any given place, a type is descended from the same view of an ancestor as that from which the current view of its parent is descended. This view determines what characteristics are inherited from the ancestor, and, for example, whether the type is considered to be a descendant of a record type, or a descendant only through record extensions of a more distant ancestor.

{AI05-0115-1} [It is possible for there to be places where a derived type is visibly a descendant of an ancestor type, but not a descendant of even a partial view of the ancestor type, because the parent of the derived type is not visibly a descendant of the ancestor. In this case, the derived type inherits no characteristics from that ancestor, but nevertheless is within the derivation class of the ancestor for the purposes of type conversion, the "covers" relationship, and matching against a formal derived type. In this case the derived type is considered to be a descendant of an incomplete view of the ancestor.]

Discussion: Here is an example of this situation:

```ada
package P
is
    type T is private;
    C : constant T;
private
    type T is new Integer;
    C : constant T := 42;
end P;
with P;
package Q is
    type T2 is new P.T;
end Q;
with Q;
package P.Child is
    Int : Integer := 52;
    V : T3 := T3(P.C); -- Legal: conversion allowed
    W : T3 := T3(Int); -- Legal: conversion allowed
    X : T3 := T3(42); -- Error: T3 is not a numeric type
    Y : T3 := X + 1; -- Error: no visible "+" operator
    Z : T3 := T3(Integer(W) + 1); -- Legal: convert to Integer first
end P.Child;
```

{8652/0019} {AI95-00033-01} {AI05-0029-1} Inherited primitive subprograms follow a different rule. For a derived_type_definition, each inherited primitive subprogram is implicitly declared at the earliest place, if any, immediately within the declarative region in which the type declaration occurs, but after the type declaration, where the corresponding declaration from the parent is visible. If there is no such place, then the inherited subprogram is not declared at all, but it still exists. [For a tagged type, it is possible to dispatch to an inherited subprogram that is not declared at all, but cannot be named in a call and cannot be overridden, but for a tagged type, it is possible to dispatch to it.]
For a private_extension_declaration, each inherited subprogram is declared immediately after the private_extension_declaration if the corresponding declaration from the ancestor is visible at that place. Otherwise, the inherited subprogram is not declared for the private extension, [though it might be for the full type].

**Reason:** There is no need for the “earliest place immediately within the declarative region within the immediate scope” business here, because a private_extension_declaration will be completed with a full_type_declaration, so we can hang the necessary private implicit declarations on the full_type_declaration.

**Discussion:** The above rules matter only when the component type (or parent type) is declared in the visible part of a package, and the composite type (or derived type) is declared within the declarative region of that package (possibly in a nested package or a child package).

Consider:

```ada
package Parent is
    type Root is tagged null record;
    procedure Op1(X : Root);
    type My_Int is range 1..10;
    private
        procedure Op2(X : Root);
        type Another_Int is new My_Int;
        procedure Int_Op(X : My_Int);
    end Parent;

    with Parent; use Parent;

package Unrelated is
    type T2 is new Root with null record;
    procedure Op2(X : T2);
end Unrelated;

package Parent.Child is
    type T3 is new Root with null record;
    -- Op1(T3) implicitly declared here.
    package Nested is
        type T4 is new Root with null record;
        private
            ...
        end Nested;
    end Parent.Child;

    with Unrelated; use Unrelated;

package body Parent.Child is
    package body Nested is
        -- Op2(T4) implicitly declared here.
    end Nested;
    type T5 is new T2 with null record;
end Parent.Child;
```

Another_Int does not inherit Int_Op, because Int_Op does not “exist” at the place where Another_Int is declared.

Type T2 inherits Op1 and Op2 from Root. However, the inherited Op2 is never declared, because Parent.Op2 is never visible immediately within the declarative region within the immediate scope of T2. T2 explicitly declares its own Op2, but this is unrelated to the inherited one — it does not override the inherited one, and occupies a different slot in the type descriptor.

T3 inherits both Op1 and Op2. Op1 is implicitly declared immediately after the type declaration, whereas Op2 is declared at the beginning of the private part. Note that if Child were a private child of Parent, then Op1 and Op2 would both be implicitly declared immediately after the type declaration.

T4 is similar to T3, except that the earliest place immediately within the declarative region containing T4 is within T4’s immediate scope where Root’s Op2 is visible in the body of Nested.

If T3 or T4 were to declare a type-conformant Op2, this would override the one inherited from Root. This is different from the situation with T2.

T5 inherits Op1 and two Op2’s from T2. Op1 is implicitly declared immediately after the declaration of T5, as is the Op2 that came from Unrelated.Op2. However, the Op2 that originally came from Parent.Op2 is never implicitly declared for T5, since T2’s version of that Op2 is never visible (anywhere — it never got declared either).

For all of these rules, implicit private parts and bodies are assumed as needed.
It is possible for characteristics of a type to be revealed in more than one place:

package P is
  type Comp1 is private;
private
  type Comp1 is new Boolean;
end P;

package P.Q is
  package R is
    type Comp2 is limited private;
    type A is array (Integer range <>) of Comp2;
private
    type Comp2 is new Comp1;
    -- A becomes nonlimited here.
    -- "a"(A, A) return Boolean is implicitly declared here.
    ...
private
  -- Now we find out what Comp1 really is, which reveals
  -- more information about Comp2, but we're not within
  -- the immediate scope of Comp2, so we don't do anything
  -- about it yet.
end R;
end P.Q;

package body P.Q is
  package body R is
    -- Things like "xor"(A,A) return A are implicitly
    -- declared here.
end R;
end P.Q;

We say immediately within the declarative region in order that types do not gain operations within a nested scope. Consider:

package Outer is
  package Inner is
    type Inner_Type is private;
    type Inner_Type is new Boolean;
  end Inner;
  type Outer_Type is array (Natural range <>) of Inner.Inner_Type;
end Outer;

package body Outer is
  package body Inner is
    -- At this point, we can see that Inner_Type is a Boolean type.
    -- But we don't want Outer_Type to gain an "and" operator here.
  end Inner;
end Outer;

The Class attribute is defined for tagged subtypes in 3.9. In addition, for every subtype S of an untagged private type whose full view is tagged, the following attribute is defined:

S'Class Denotes the class-wide subtype corresponding to the full view of S. This attribute is allowed only from the beginning of the private part in which the full view is declared, until the declaration of the full view. [After the full view, the Class attribute of the full view can be used.]

NOTES

9 Because a partial view and a full view are two different views of one and the same type, outside of the defining package the characteristics of the type are those defined by the visible part. Within these outside program units the type is just a private type or private extension, and any language rule that applies only to another class of types does not apply. The fact that the full declaration might implement a private type with a type of a particular class (for example, as an array type) is relevant only within the declarative region of the package itself including any child units.

10 The consequences of this actual implementation are, however, valid everywhere. For example: any default initialization of components takes place; the attribute Size provides the size of the full view; finalization is still done for controlled components of the full view; task dependence rules still apply to components that are task objects.

10 Partial views provide initialization assignment (unless the view is limited), membership tests, selected components for the selection of discriminants and inherited components, qualification, and explicit conversion. Nonlimited partial views also allow use of assignment statements.
11 For a subtype S of a partial view, S'Size is defined (see 13.3). For an object A of a partial view, the attributes A'Size and A'Address are defined (see 13.3). The Position, First_Bit, and Last_Bit attributes are also defined for discriminants and inherited components.

### Examples

#### Example of a type with private operations:

```ada
package Key_Manager is
  type Key is private;
  Null_Key : constant Key;  -- a deferred constant declaration (see 7.4)
  procedure Get_Key(K : out Key);
  function "<" (X, Y : Key) return Boolean;
private
  type Key is new Natural;
  Null_Key : constant Key := Key'First;
end Key_Manager;

package body Key_Manager is
  Last_Key : Key := Null_Key;
  procedure Get_Key(K : out Key) is
    begin
      Last_Key := Last_Key + 1;
      K := Last_Key;
      Get_Key;
  end Get_Key;
  function "<" (X, Y : Key) return Boolean is
    begin
      return Natural(X) < Natural(Y);
    end "<";
end Key_Manager;
```

Notes

12 Notes on the example: Outside of the package Key_Manager, the operations available for objects of type Key include assignment, the comparison for equality or inequality, the procedure Get_Key and the operator "<", they do not include other relational operators such as ">=", or arithmetic operators.

The explicitly declared operator "<" hides the predefined operator "<" implicitly declared by the full_type_declaration. Within the body of the function, an explicit conversion of X and Y to the subtype Natural is necessary to invoke the "<" operator of the parent type. Alternatively, the result of the function could be written as not (X >= Y), since the operator ">=" is not redefined.

The value of the variable Last_Key, declared in the package body, remains unchanged between calls of the procedure Get_Key. (See also the NOTES of 7.2.)

### Wording Changes from Ada 83

The phrase in RM83-7.4.2(7), "...after the full type declaration", doesn’t work in the presence of child units, so we define that rule in terms of visibility.

The definition of the Constrained attribute for private types has been moved to “Obsolescent Features.” (The Constrained attribute of an object has not been moved there.)

### Wording Changes from Ada 95

{8652/0018} {AI95-00033-01} **Corrigendum:** Clarified when additional operations are declared.

{AI95-00287-01} Revised the note on operations of partial views to reflect that limited types do have an assignment operation, but not assignment statements.

### Wording Changes from Ada 2005

{AI05-0029-1} **Correction:** Revised the wording to say that predefined operations still exist even if they are never declared, because it is possible to reference them in a generic unit.

{AI05-0115-1} **Correction:** Clarified that the characteristics of a descendant of a private type depend on the visibility of the full view of the direct ancestor. This has to be the case (so that privacy is not violated), but it wasn’t spelled out in earlier versions of Ada.
7.3.2 Type Invariants

For a private type or private extension, the following language-defined aspects may be specified with an aspect specification (see 13.1.1):

Type Invariant

This aspect shall be specified by an expression, called an invariant expression. Type Invariant may be specified on a private type declaration, on a private extension declaration, or on a full type declaration that declares the completion of a private type or private extension.

Aspect Description for Type_Invariant: A condition that must hold true for all objects of a type.

Type_Invariant'Class

This aspect shall be specified by an expression, called an invariant expression. Type_Invariant'Class may be specified on a private type declaration or a private extension declaration.

Reason: A class-wide type invariant cannot be hidden in the private part, as the creator of an extension needs to know about it in order to conform to it in any new or overriding operations. On the other hand, a specific type invariant is not inherited, so that no operation outside of the original package needs to conform to it; thus there is no need for it to be visible.

Aspect Description for Type_Invariant'Class: A condition that must hold true for all objects in a class of types.

Name Resolution Rules

The expected type for an invariant expression is any boolean type.

Within an invariant expression, the identifier of the first subtype of the associated type denotes the current instance of the type. Within an invariant expression associated with type \( T \), the type of the current instance is \( T \) for the Type_Invariant aspect and \( T'\text{Class} \) for the Type_Invariant'Class aspect.

Proof: The first sentence is given formally in 13.1.1.

Legality Rules

The Type_Invariant'Class aspect shall not be specified for an untagged type. The Type_Invariant aspect shall not be specified for an abstract type.

Proof: The first sentence is given formally in 13.1.1.

Static Semantics

If the Type_Invariant aspect is specified for a type \( T \), then the invariant expression applies to \( T \).

If the Type_Invariant'Class aspect is specified for a tagged type \( T \), then the invariant expression applies to all descendants of \( T \).

Proof: "Applies" is formally defined in 13.1.1.

Dynamic Semantics

If one or more invariant expressions apply to a type \( T \), then an invariant check is performed at the following places, on the specified object(s):

- After successful default initialization of an object of type \( T \), the check is performed on the new object;
- After successful conversion to type \( T \), the check is performed on the result of the conversion;
• \{AI05-0146-1\} \{AI05-0269-1\} For a view conversion, outside the immediate scope of \texttt{T}, that converts from a descendant of \texttt{T} (including \texttt{T} itself) to an ancestor of type \texttt{T} (other than \texttt{T} itself), a check is performed on the part of the object that is of type \texttt{T}:
  
  • after assigning to the view conversion; and
  
  • after successful return from a call that passes the view conversion as an \texttt{in out} or \texttt{out} parameter.

  \textbf{Ramification:} For a single view conversion that converts between distantly related types, this rule could be triggered for multiple types and thus multiple invariant checks may be needed.

  \textbf{Implementation Note: \{AI05-0299-1\}} For calls to inherited subprograms (including dispatching calls), the implied view conversions mean that a wrapper is probably needed. (See the Note at the bottom of this subclause for more on the model of checks for inherited subprograms.)

  For view conversions involving class-wide types, the exact checks needed may not be known at compile-time. One way to deal with this is to have an implicit dispatching operation that is given the object to check and the tag of the target of the conversion, and which first checks if the passed tag is not for itself, and if not, checks the its invariant on the object and then calls the operation of its parent type. If the tag is for itself, the operation is complete.

• After a successful call on the \texttt{Read} or \texttt{Input} stream attribute of the type \texttt{T}, the check is performed on the object initialized by the stream attribute;

• \{AI05-0146-1\} \{AI05-0269-1\} An invariant is checked upon successful return from a call on any subprogram or entry that:
  
  • \{AI05-0146-1\} \{AI05-0269-1\} is declared within the immediate scope of type \texttt{T} (or by an instance of a generic unit, and the generic is declared within the immediate scope of type \texttt{T}), and
  
  • is visible outside the immediate scope of type \texttt{T} or overrides an operation that is visible outside the immediate scope of \texttt{T}, and
  
  • \{AI05-0289-1\} has a result with a part of type \texttt{T}, or one or more parameters with a part of type \texttt{T}, or an access to variable parameter whose designated type has a part of type \texttt{T}.

• \{AI05-0146-1\} \{AI05-0269-1\} The check is performed on each such part of type \texttt{T}.

\{AI05-0290-1\} If performing checks is required by the Invariant or Invariant'Class assertion policies (see 11.4.2) in effect at the point of corresponding aspect specification applicable to a given type, then the respective invariant expression is considered \textit{enabled}.

  \textbf{Ramification:} If a class-wide invariant expression is enabled for a type, it remains enabled when inherited by descendants of that type, even if the policy in effect is Ignore for the inheriting type.

\{AI05-0146-1\} \{AI05-0250-1\} \{AI05-0289-1\} \{AI05-0290-1\} The invariant check consists of the evaluation of each enabled invariant expression that applies to \texttt{T}, on each of the objects specified above. If any of these evaluate to False, \texttt{Assertions.Assertion_Error} is raised at the point of the object initialization, conversion, or call. If a given call requires more than one evaluation of an invariant expression, either for multiple objects of a single type or for multiple types with invariants, the evaluations are performed in an arbitrary order, and if one of them evaluates to False, it is not specified whether the others are evaluated. Any invariant check is performed prior to copying back any by-copy \texttt{in out} or \texttt{out} parameters. Invariant checks, any postcondition check, and any constraint or predicate checks associated with \texttt{in out} or \texttt{out} parameters are performed in an arbitrary order.

\{AI05-0146-1\} \{AI05-0247-1\} \{AI05-0250-1\} The invariant checks performed on a call are determined by the subprogram or entry actually invoked, whether directly, as part of a dispatching call, or as part of a call through an access-to-subprogram value.

  \textbf{Ramification:} Invariant checks on subprogram return are not performed on objects that are accessible only through access values. It is also possible to call through an access-to-subprogram value and reach a subprogram body that has visibility on the full declaration of a type, from outside the immediate scope of the type. No invariant checks will be performed if the designated subprogram is not itself externally visible. These cases represent "holes" in the protection...
provided by invariant checks; but note that these holes cannot be caused by clients of the type \( T \) with the invariant without help for the designer of the package containing \( T \).

**Implementation Note:** The implementation might want to produce a warning if a private extension has an ancestor type that is a visible extension, and an invariant expression depends on the value of one of the components from a visible extension part.

**NOTES**

13  \{AI05-0250-1\} \{AI05-0269-1\} For a call of a primitive subprogram of type \( NT \) that is inherited from type \( T \), the specified checks of the specific invariants of both the types \( NT \) and \( T \) are performed. For a call of a primitive subprogram of type \( NT \) that is overridden for type \( NT \), the specified checks of the specific invariants of only type \( NT \) are performed.

**Proof:** This follows from the definition of a call on an inherited subprogram as view conversions of the parameters of the type and a call to the original subprogram (see 3.4), along with the normal invariant checking rules. In particular, the call to the original subprogram takes care of any checks needed on type \( T \); and the checks required on view conversions take care of any checks needed on type \( NT \), specifically on in out and out parameters. We require this in order that the semantics of an explicitly defined wrapper that does nothing but call the original subprogram is the same as that of an inherited subprogram.

### 7.4 Deferred Constants

[Deferred constant declarations may be used to declare constants in the visible part of a package, but with the value of the constant given in the private part. They may also be used to declare constants imported from other languages (see Annex B).]

**Legality Rules**

2.\{AI05-0229-1\} \{AI05-0269-1\} [ A deferred constant declaration is an object declaration with the reserved word constant but no initialization expression.] The constant declared by a deferred constant declaration is called a deferred constant. [Unless the Import aspect (see B.1) is True for a deferred constant declaration, the deferred constant declaration requires a completion, which shall be a full constant declaration (called the full declaration of the deferred constant), or a pragma Import (see Annex B).]

2.a Proof: The first sentence is redundant, as it is stated officially in 3.3.1.

2.b/3 \{AI05-0229-1\} \{AI05-0269-1\} The first part of the last sentence is redundant, as no imported entity may have a completion, as stated in B.1.

3 A deferred constant declaration that is completed by a full constant declaration shall occur immediately within the visible part of a package specification. For this case, the following additional rules apply to the corresponding full declaration:

- The full declaration shall occur immediately within the private part of the same package;
- \{AI95-00385-01\} The deferred and full constants shall have the same type, or shall have statically matching anonymous access subtypes;
- \{AI95-00385-01\} \{AI95-0062-1\} \{AI05-0262-1\} If the deferred constant declaration includes a subtype defined by the subtype indication \( S \) that defines an the deferred declaration is constrained subtype, then the constraint subtype defined by the subtype indication in the full declaration shall match the constraint defined by \( S \) statically. On the other hand, if the subtype of the deferred constant is unconstrained, then the full declaration is still allowed to impose a constraint. The constant itself will be constrained, like all constants;]

### Extensions to Ada 2005

\{AI05-0146-1\} \{AI05-0247-1\} \{AI05-0250-1\} \{AI05-0289-1\} Type_Invariant aspects are new.
• \{AI95-00231-01\} If the deferred constant declaration includes the reserved word **aliased**, then the full declaration shall also.

  **Ramification:** On the other hand, the full constant can be aliased even if the deferred constant is not.

• \{AI95-00231-01\} If the subtype of the deferred constant declaration excludes null, the subtype of the full declaration shall also exclude null.

  **Ramification:** On the other hand, the full constant can exclude null even if the deferred constant does not. But that can only happen for a **subtype_indication**, as anonymous access types are required to statically match (which includes any **null_exclusion**).

\{AI05-0229-1\} [A deferred constant declaration **for which the** aspect is **Import** need not appear in the visible part of a **package_specification**, and has no full constant declaration.]

\{AI95-00256-01\} The completion of a deferred constant declaration shall occur before the constant is frozen (see 13.14.4).

Dynamic Semantics

\{AI05-0004-1\} The elaboration of a deferred constant declaration elaborates the **subtype_indication**, **access_definition**, or (only allowed in the case of an imported constant) the **array_type_definition**.

  **Ramification:** \{AI05-0004-1\} For nonimported constants, these elaborations cannot require any code or checks for a legal program, because the given subtype_indication has to be indefinite or statically match that of the full constant, meaning that either it is a subtype_mark or it has static constraints. If the deferred constant instead has an access_definition, the designated subtype must be a subtype_mark. We still say that these are elaborated, however, because part of elaboration is creating the type, which is clearly needed for access definitions. (A deferred constant and its full constant have different types when they are specified by an access_definition, although there is no visible effect of these types being different as neither can be named.)

NOTES

14 The full constant declaration for a deferred constant that is of a given private type or private extension is not allowed before the corresponding full_type_declaration. This is a consequence of the freezing rules for types (see 13.14).

  **Ramification:** Multiple or single declarations are allowed for the deferred and the full declarations, provided that the equivalent single declarations would be allowed.

  Deferred constant declarations are useful for declaring constants of private views, and types with components of private views. They are also useful for declaring access-to-constant objects that designate variables declared in the private part of a package.

Examples

**Examples of deferred constant declarations:**

Null_Key : constant Key;  -- see 7.3.1

\{AI05-0229-1\} CPU_Identifier : constant String(1..8) :=

with pragma Import => True, Convention => (Assembler, CPU_Identifier, Link_Name => "CPU_ID");

  -- see B.1

Extensions to Ada 83

In Ada 83, a deferred constant is required to be of a private type declared in the same visible part. This restriction is removed for Ada 95; deferred constants can be of any type.

In Ada 83, a deferred constant declaration was not permitted to include a constraint, nor the reserved word **aliased**.

In Ada 83, the rules required conformance of type marks; here we require static matching of subtypes if the deferred constant is constrained.

A deferred constant declaration can be completed with a **pragma Import.** Such a deferred constant declaration need not be within a **package_specification.**

The rules for too-early uses of deferred constants are modified in Ada 95 to allow more cases, and catch all errors at compile time. This change is necessary in order to allow deferred constants of a tagged type without violating the principle that for a dispatching call, there is always an implementation to dispatch to. It has the beneficial side effect of
catching some Ada-83-erroneous programs at compile time. The new rule fits in well with the new freezing-point rules. Furthermore, we are trying to convert undefined-value problems into bounded errors, and we were having trouble for the case of deferred constants. Furthermore, uninitialized deferred constants cause trouble for the shared variable/tasking rules, since they are really variable, even though they purport to be constant. In Ada 95, they cannot be touched until they become constant.

Note that we do not consider this change to be an upward incompatibility, because it merely changes an erroneous execution in Ada 83 into a compile-time error.

The Ada 83 semantics are unclear in the case where the full view turns out to be an access type. It is a goal of the language design to prevent uninitialized access objects. One wonders if the implementation is required to initialize the deferred constant to null, and then initialize it (again!) to its real value. In Ada 95, the problem goes away.

**Wording Changes from Ada 83**

\{AI03-0299-1\} Since deferred constants can now be of a nonprivate type, we have made this a stand-alone subclause, rather than a subclause of 7.3, “Private Types and Private Extensions”.

Deferred constant declarations used to have their own syntax, but now they are simply a special case of object declarations.

**Extensions to Ada 95**

\{AI95-00385-01\} Deferred constants were enhanced to allow the use of anonymous access types in them.

**Wording Changes from Ada 95**

\{AI95-00231-01\} Added matching rules for subtypes that exclude null.

**Wording Changes from Ada 2005**

\{AI05-0062-1\} Correction: Corrected rules so that the intent that a full constant may have a null exclusion even if the deferred constant does not is actually met.

### 7.5 Limited Types

\{AI95-00287-01\} [A limited type is (a view of) a type for which copying (such as for an assignment statement) the assignment operation is not allowed. A nonlimited type is a (view of) a type for which copying the assignment operation is allowed.]

**Discussion:** The concept of the value of a limited type is difficult to define, since the abstract value of a limited type often extends beyond its physical representation. In some sense, values of a limited type cannot be divorced from their object. The value is the object.

\{AI95-00318-02\} In Ada 83, in the two places where limited types were defined by the language, namely tasks and files, an implicit level of indirection was implied by the semantics to avoid the separation of the value from an associated object. In Ada 95, most limited types are passed by reference, and even return-ed by reference. In Ada 2005, most limited types are built-in-place upon return, rather than returned by reference. Thus the object “identity” is part of the logical value of most limited types.

**To be honest:** \{AI95-00287-01\} \{AI95-00419-01\} For a limited partial view whose full view is nonlimited, copying assignment is possible on parameter passing and function return. To prevent any copying whatsoever, one should make both the partial and full views limited.

**Glossary entry:** A limited type is (a view of) a type for which copying (such as in an assignment statement) the assignment operation is not allowed. A nonlimited type is a (view of a) type for which copying the assignment operation is allowed.

**Legality Rules**

\{AI95-00419-01\} If a tagged record type has any limited components, then the reserved word limited shall appear in its record_type_definition. [If the reserved word limited appears in the definition of a derived_type_definition, its parent type and any progenitor interfaces shall be limited.]

**Proof:** \{AI95-00419-01\} The rule about the parent type being required to be limited can be found in 3.4. Rules about progenitor interfaces can be found in 3.9.4, specifically, a nonlimited interface can appear only on a nonlimited type. We repeat these rules here to gather these scattered rules in one obvious place.
Reason: This prevents tagged limited types from becoming nonlimited. Otherwise, the following could happen:

```ada
package P is
  type T is limited private;
  type R is tagged
    record -- Illegal!
      X : T;
    end record;
private
  type T is new Integer; -- R becomes nonlimited here.
end P;
package Q is
  type R2(Access_Discrim : access ...) is new R with
    record
      Y : Some_Task_Type;
    end record;
end Q;
```

This should say "limited record".

X : T;
end record;

private
type T is new Integer; -- R becomes nonlimited here.
end P;
package Q is
  type R2(Access_Discrim : access ...) is new R with
    record
      Y : Some_Task_Type;
    end record;
end Q;

{AI95-00230-01} If the above were legal, then assignment would be defined for R’Class in the body of P, which is bad news, given the access discriminant and the task.

{AI95-00287-01} {AI95-00318-02} {AI05-0147-1} In the following contexts, an expression of a limited type is not permitted unless it is an aggregate, a function call, or a parenthesized expression or qualified expression whose operand is permitted by this rule, or a conditional expression all of whose dependent expressions are permitted by this rule:

- the initialization expression of an object declaration (see 3.3.1)
- the default_expression of a component_declaration (see 3.8)
- the expression of a record_component_association (see 4.3.1)
- the expression for an ancestor_part of an extension_aggregate (see 4.3.2)
- an expression of a positional_array_aggregate or the expression of an array_component_association (see 4.3.3)
- the qualified_expression of an initialized allocator (see 4.8)
- the expression of a return statement (see 6.5)
- the expression of an expression_function_declaration (see 6.8)
- the default_expression or actual parameter for a formal object of mode in (see 12.4)

Discussion: All of these contexts normally require copying; by restricting the uses as above, we can require the new object to be built-in-place.

Static Semantics

{AI95-00419-01} {AI05-0178-1} A view of a type is limited if it is a descendant of one of the following:

- a type with the reserved word limited, synchronized, task, or protected in its definition;

Ramification: Note that there is always a “definition,” conceptually, even if there is no syntactic category called “..._definition”.

{AI95-00419-01} This includes interfaces of the above kinds, derived types with the reserved word limited, as well as task and protected types.

- a class-wide type whose specific type is limited;

This paragraph was deleted a task or protected type;

- a composite type with a limited component;

- an incomplete view;

- a derived type whose parent is limited and is not an interface.
Limitedness is not inherited from interfaces; it must be explicitly specified when the parent is an interface.

A derived type can become nonlimited if limited does not appear and the derivation takes place in the visible part of a child package, and the parent type is nonlimited as viewed from the private part or body of the child package.

We considered a rule where limitedness was always inherited from the parent for derived types, but in the case of a type whose parent is an interface, this meant that the first interface is treated differently than other interfaces. It also would have forced users to declare dummy nonlimited interfaces just to get the limitedness right. We also considered a syntax like not limited to specify nonlimitedness when the parent was limited, but that was unsavory. The rule given is more uniform and simpler to understand.

The rules for interfaces are asymmetrical, but the language is not: if the parent interface is limited, the presence of the word limited determines the limitedness, and nonlimited progenitors are illegal by the rules in 3.9.4 if limited is present. If the parent interface is nonlimited, the word limited is illegal by the rules in 3.4. The net effect is that the order of the interfaces doesn't matter.

Otherwise, the type is nonlimited.

A type is immutably limited if it is one of the following:

- An explicitly limited record type;
- A record extension with the reserved word limited;
- A nonformal limited private type that is tagged or has at least one access discriminant with a default expression;
- A task type, a protected type, or a synchronized interface;
- A type derived from an immutably limited type.

An immutably limited type is a type that cannot become nonlimited subsequently in a private part or in a child unit. If a view of the type makes it immutably limited, then no copying (assignment) operations are ever available for objects of the type. This allows other properties; for instance, it is safe for such objects to have access discriminants that have defaults or designate other limited objects.

A nonsynchronized limited interface type is not immutably limited; a type derived from it can be nonlimited.

A descendant of a generic formal limited private type is presumed to be immutably limited except within the body of a generic unit or a body declared within the declarative region of a generic unit, if the formal type is declared within the formal part of the generic unit.

In an instance, a type is descended from the actual type corresponding to the formal, and all rules are rechecked in the specification. Bodies are excepted so that we assume the worst there; the complex wording is required to handle children of generics and unrelated bodies properly.

For an aggregate of a limited type used to initialize an object as allowed above, the implementation shall not create a separate anonymous object for the aggregate. For a function_call of a type with a part that is of a task, protected, or explicitly limited record type that is used to initialize an object as allowed above, the implementation shall not create a separate return object (see 6.5) for the function_call. The aggregate or function_call shall be constructed directly in the new object.

For a function_call, we only require build-in-place for a limited type that would have been a return-by-reference type in Ada 95. We do this because we want to minimize disruption to Ada 95 implementations and users.
NOTES
15 {AI95-00287-01} {AI95-00318-02} {AI05-0067-1} While it is allowed to write initializations of limited objects, such initializations never copy a limited object. The source of such an assignment operation must be an aggregate or function_call, and such aggregates and function_calls must be built directly in the target object (see 7.6). The following are consequences of the rules for limited types:

   To be honest: This isn't quite true if the type can become nonlimited (see below); function_calls only are required to be build-in-place for "really" limited types.

Paragraphs 10 through 15 were deleted.

• {AI95-00287-01} An initialization expression is not allowed in an object_declaration if the type of the object is limited.

• {AI95-00287-01} A default_expression is not allowed in a component_declaration if the type of the record component is limited.

• {AI95-00287-01} An initialized allocator is not allowed if the designated type is limited.

• {AI95-00287-01} A generic formal parameter of mode in must not be of a limited type.

16 {AI95-00287-01} Aggregates are not available for a limited composite type. Concatenation is not available for a limited array_type.

17 {AI95-00287-01} The rules do not exclude a default_expression for a formal parameter of a limited type; they do not exclude a deferred constant of a limited type if the full declaration of the constant is of a nonlimited type.

18 As illustrated in 7.3.1, an untagged limited type can become nonlimited under certain circumstances.

   Ramification: Limited private types do not become nonlimited; instead, their full view can be nonlimited, which has a similar effect.

   It is important to remember that a single nonprivate type can be both limited and nonlimited in different parts of its scope. In other words, “limited” is a property that depends on where you are in the scope of the type. We don't call this a "view property" because there is no particular declaration to declare the nonlimited view.

   Tagged types never become nonlimited.

Examples

Example of a package with a limited type:

package IO_Package is
   type File_Name is limited private;
   procedure Open (F : in out File_Name);
   procedure Close(F : in out File_Name);
   procedure Read (F : in File_Name; Item : out Integer);
   procedure Write(F : in File_Name; Item : in Integer);
private
   type File_Name is limited record
      Internal_Name : Integer := 0;
   end record;
end IO_Package;
package body IO_Package is
   Limit : constant := 200;
   type File_Descriptor is record ... end record;
   Directory : array (1 .. Limit) of File_Descriptor;
   ... procedure Open (F : in out File_Name) is ... end;
   procedure Close(F : in out File_Name) is ... end;
   procedure Read (F : in File_Name; Item : out Integer) is ... end;
   procedure Write(F : in File_Name; Item : in Integer) is ... end;
begin
   ... end IO_Package;
NOTES
19 Notes on the example: In the example above, an outside subprogram making use of IO_Package may obtain a file name by calling Open and later use it in calls to Read and Write. Thus, outside the package, a file name obtained from Open acts as a kind of password; its internal properties (such as containing a numeric value) are not known and no other operations (such as addition or comparison of internal names) can be performed on a file name. Most importantly, clients of the package cannot make copies of objects of type File_Name.
This example is characteristic of any case where complete control over the operations of a type is desired. Such packages serve a dual purpose. They prevent a user from making use of the internal structure of the type. They also implement the notion of an encapsulated data type where the only operations on the type are those given in the package specification.

The fact that the full view of File_Name is explicitly declared limited means that parameter passing and function return will always be by reference and function results will always be built directly in the result object (see 6.2 and 6.5).

Extensions to Ada 83

The restrictions in RM83-7.4.4(4), which disallowed out parameters of limited types in certain cases, are removed.

Wording Changes from Ada 83

Extensions to Ada 95

Limited types now have an assignment operation, but its use is restricted such that all uses are build-in-place. This is accomplished by restricting uses to aggregates and function calls. Aggregates were not allowed to have a limited type in Ada 95, which causes a compatibility issue discussed in 4.3, “Aggregates”. Compatibility issues with return statements for limited function calls are discussed in 6.5, “Return Statements”.

Wording Changes from Ada 95

Rewrote the definition of limited to ensure that interfaces are covered, but that limitedness is not inherited from interfaces. Derived types that explicitly include limited are now also covered.

Wording Changes from Ada 2005

Correction: Added a definition for immutably limited types, so that the fairly complex definition does not need to be repeated in rules elsewhere in the Standard.

Correction: The built-in-place rules are consolidated in 7.6, and thus they are removed from this subclause.

Correction: Fixed an oversight: class-wide types were never defined to be limited, even if their associated specific type is. It is thought that this oversight was never implemented incorrectly by any compiler, thus we have not classified it as an incompatibility.

Allowed conditional expressions in limited constructor contexts — we want to treat these as closely to parentheses as possible.

Added wording so that expression functions can return limited entities.

Correction: Added incomplete views to the list of reasons for a view of a type to be limited. This is not a change as the definition already was in 3.10.1. But it is much better to have all of the reasons for limitedness together.

7.6 Assignment and Finalization

User-Defined Assignment and Finalization

Three kinds of actions are fundamental to the manipulation of objects: initialization, finalization, and assignment. Every object is initialized, either explicitly or by default, after being created (for example, by an object_declaration or allocator). Every object is finalized before being destroyed (for example, by leaving a subprogram_body containing an object_declaration, or by a call to an instance of Unchecked_Deallocation). An assignment operation is used as part of assignment_statements, explicit initialization, parameter passing, and other operations.

Default definitions for these three fundamental operations are provided by the language, but a controlled type gives the user additional control over parts of these operations. In particular, the user can define, for a controlled type, an Initialize procedure which is invoked immediately after the normal default initialization of a controlled object, a Finalize procedure which is invoked immediately before finalization.
of any of the components of a controlled object, and an Adjust procedure which is invoked as the last step of an assignment to a (nonlimited) controlled object.

**Glossary entry:** A controlled type supports user-defined assignment and finalization. Objects are always finalized before being destroyed.

**Ramification:** [AI95-00114-01] [AI95-00287-01] Here's the basic idea of initialization, value adjustment, and finalization, whether or not user defined: When an object is created, if it is explicitly assigned an initial value, the object is either built-in-place from an aggregate or function call (in which case neither Adjust nor Initialize is applied), or the assignment copies and adjusts the initial value. Otherwise, Initialize is applied to it (except in the case of an aggregate as a whole). An assignment_statement finalizes the target before copying in and adjusting the new value. Whenever an object goes away, it is finalized. Calls on Initialize and Adjust happen bottom-up; that is, components first, followed by the containing object. Calls on Finalize happen top-down; that is, first the containing object, and then its components. These ordering rules ensure that any components will be in a well-defined state when Initialize, Adjust, or Finalize is applied to the containing object.

**Static Semantics**

The following language-defined library package exists:

```ada
pragma Pure, Preelaborate (Finalization);
pragma Remote_Types (Finalization);
package Ada.Finalization is
  pragma Preelaborable_Initialization (Controlled);
  type Controlled is abstract tagged private;
  procedure Initialize (Object : in out Controlled) is null;
  procedure Finalize (Object : in out Controlled) is null;
private
  ... -- not specified by the language
end Ada.Finalization;
```

{AI95-00348-01} A controlled type is a descendant of Controlled or Limited_Controlled. The (default) implementations of Initialize, Adjust, and Finalize have no effect. The predefined "=" operator of type Controlled always returns True, [since this operator is incorporated into the implementation of the predefined equality operator of types derived from Controlled, as explained in 4.5.2.] The type Limited_Controlled is like Controlled, except that it is limited and it lacks the primitive subprogram Adjust.

**Discussion:** We say "nonlimited controlled type" (rather than just "controlled type"); when we want to talk about descendants of Controlled only.

**Reason:** We considered making Adjust and Finalize abstract. However, a reasonable coding convention is e.g. for Finalize to always call the parent's Finalize after doing whatever work is needed for the extension part. (Unlike CLOS, we have no way to do that automatically in Ada 95.) For this to work, Finalize cannot be abstract. In a generic unit, for a generic formal abstract derived type whose ancestor is Controlled or Limited_Controlled, calling the ancestor's Finalize would be illegal if it were abstract, even though the actual type might have a concrete version.

Types Controlled and Limited_Controlled are abstract, even though they have no abstract primitive subprograms. It is not clear that they need to be abstract, but there seems to be no harm in it, and it might make an implementation's life easier to know that there are no objects of these types — in case the implementation wishes to make them "magic" in some way.

{AI95-00348-01} For Ada 2005, we considered making these types interfaces. That would have the advantage of allowing them to be added to existing trees. But that was rejected both because it would cause massive disruptions to existing implementations, and because it would be very incompatible due to the "no hidden interfaces" rule. The latter rule would prevent a tagged private type from being completed with a derivation from Controlled or Limited_Controlled — a very common idiom.

{AI95-00360-01} A type is said to need finalization if:
7.6 Assignment and Finalization

- it is a controlled type, a task type or a protected type; or
- \{AI05-0092-1\} it has a component whose type needs finalization; or
- \{AI05-0013-1\} it is a class-wide type; or it is a limited type that has an access discriminant whose designated type needs finalization; or
- \{AI05-0026-1\} it is a partial view whose full view needs finalization; or
- it is one of a number of language-defined types that are explicitly defined to need finalization.

**Ramification:** The fact that a type needs finalization does not require it to be implemented with a controlled type. It just has to be recognized by the No_Nested_Finalization restriction.

This property is defined for the type, not for a particular view. That's necessary as restrictions look in private parts to enforce their restrictions; the point is to eliminate all controlled parts, not just ones that are visible.

**Dynamic Semantics**

\{AI95-00373-01\} During the elaboration or evaluation of a construct that causes an object to be initialized by default of an object declaration, for every controlled subcomponent of the object that is not assigned an initial value (as defined in 3.3.1), Initialize is called on that subcomponent. Similarly, if the object that is initialized by default as a whole is controlled and is not assigned an initial value, Initialize is called on the object. The same applies to the evaluation of an allocator, as explained in 4.8.

\{8652/0021\} \{AI95-00182-01\} \{AI95-00373-01\} For an extension_aggregate whose ancestor_part is a subtype_mark denoting a for each controlled subcomponent of the ancestor_part, either Initialize is called, or its initial value is assigned, as appropriate. Initialize is called on all controlled subcomponents of the ancestor_part, if the type of the ancestor_part is itself controlled subtype, the Initialize procedure of the ancestor type is called, unless that Initialize procedure is abstract.

**Discussion:** Example:

```ada
type T1 is new Controlled with
record
    ... -- some components might have defaults
end record;

 type T2 is new Controlled with
record
    X : T1; -- no default
    Y : T1 := ...; -- default
end record;

A : T2;
B : T2 := ...;
```

As part of the elaboration of A's declaration, A.Y is assigned a value; therefore Initialize is not applied to A.Y. Instead, Adjust is applied to A.Y as part of the assignment operation. Initialize is applied to A.X and to A, since those objects are not assigned an initial value. The assignment to A.Y is not considered an assignment to A.

For the elaboration of B's declaration, Initialize is not called at all. Instead the assignment adjusts B's value; that is, it applies Adjust to B.X, B.Y, and B.

\{8652/0021\} \{AI95-00182-01\} \{AI95-00373-01\} The ancestor_part of an extension_aggregate, \(<> in aggregates, and the return object of an extended_return_statement are handled similarly.

Initialize and other initialization operations are done in an arbitrary order, except as follows. Initialize is applied to an object after initialization of its subcomponents, if any [(including both implicit initialization and Initialize calls)]. If an object has a component with an access discriminant constrained by a per-object expression, Initialize is applied to this component after any components that do not have such discriminants. For an object with several components with such a discriminant, Initialize is applied to them in order of their component_declarations. For an allocator, any task activations follow all calls on Initialize.

**Reason:** The fact that Initialize is done for subcomponents first allows Initialize for a composite object to refer to its subcomponents knowing they have been properly initialized.
The fact that Initialize is done for components with access discriminants after other components allows the Initialize operation for a component with a self-referential access discriminant to assume that other components of the enclosing object have already been properly initialized. For multiple such components, it allows some predictability.

When a target object with any controlled parts is assigned a value, [either when created or in a subsequent assignment_statement,] the assignment operation proceeds as follows:

- The value of the target becomes the assigned value.
- The value of the target is adjusted.

**Ramification:** If any parts of the object are controlled, abort is deferred during the assignment operation.

{AI05-0067-1} To adjust the value of a (nonlimited) composite object, the values of the components of the object are first adjusted in an arbitrary order, and then, if the object is nonlimited controlled, Adjust is called. Adjusting the value of an elementary object has no effect[, nor does adjusting the value of a composite object with no controlled parts.]

**Ramification:** {AI05-0067-1} Adjustment is never actually performed for values of an immutably by-reference limited type, since all assignment operations for such types are required to be built-in-place. Even so, we still define adjustment for all types in order that the canonical semantics is well-defined; these types do not support copying.

**Reason:** {AI05-0005-1} The verbiage in the Initialize rule about access discriminants constrained by per-object expressions is not necessary here, since such types are either limited or do not have defaults, so the discriminant can only be changed by an assignment to an outer object. Such an assignment could happen only before any adjustments or (if part of an outer Adjust) only after any inner (component) adjustments have completed—and therefore are never adjusted.

For an assignment_statement, [after the name and expression have been evaluated, and any conversion (including constraint checking) has been done.] an anonymous object is created, and the value is assigned into it; [that is, the assignment operation is applied]. [(Assignment includes value adjustment.)] The target of the assignment_statement is then finalized. The value of the anonymous object is then assigned into the target of the assignment_statement. Finally, the anonymous object is finalized. [As explained below, the implementation may eliminate the intermediate anonymous object, so this description subsumes the one given in 5.2, “Assignment Statements”.]

**Reason:** An alternative design for user-defined assignment might involve an Assign operation instead of Adjust:

```ada
procedure Assign(Target : in out Controlled; Source : in out Controlled);
```

Or perhaps even a syntax like this:

```ada
procedure "="(Target : in out Controlled; Source : in out Controlled);
```

Assign (or "=") would have the responsibility of doing the copy, as well as whatever else is necessary. This would have the advantage that the Assign operation knows about both the target and the source at the same time — it would be possible to do things like reuse storage belonging to the target, for example, which Adjust cannot do. However, this sort of design would not work in the case of unconstrained discriminated variables, because there is no way to change the discriminants individually. For example:

```ada
type Mutable(D : Integer := 0) is
  record
    X : Array_Of_Controlled_Things(1..D);
    case D is
      when 17 => Y : Controlled_Thing;
      when others => null;
    end D;
  end record;
```

An assignment to an unconstrained variable of type Mutable can cause some of the components of X, and the component Y, to appear and/or disappear. There is no way to write the Assign operation to handle this sort of case.

Forbidding such cases is not an option — it would cause generic contract model violations.

{AI05-0067-1} When a function call or aggregate is used to initialize an object, the result of the function call or aggregate is an anonymous object, which is assigned into the newly-created object. For such an assignment, the anonymous object might be built in place, in which case the assignment does not involve any copying. Under certain circumstances, the anonymous object is required to be built in place. In particular:
Discussion: \{AI05-0067-1\} We say assignment to built-in-place objects does not involve copying, which matches the intended implementation (see below). Of course, the implementation can do any copying it likes, if it can make such copying semantically invisible (by patching up access values to point to the copy, and so forth).

- If the full type of any part of the object is immutably limited, the anonymous object is built in place.

  Reason: \{AI05-0067-1\} We talk about the full types being immutably limited, as this is independent of the view of a type (in the same way that it is for determining the technique of parameter passing). That is, privacy is ignored for this purpose.

  \{AI05-0005-1\} \{AI05-0067-1\} For function calls, we only require building in place for immutably limited types. These are the types that would have been return-by-reference types in Ada 95. We limited the requirement because we want to minimize disruption to Ada 95 implementations and users.

  To be honest: \{AI05-0232-1\} This is a dynamic property and is determined by the specific type of the parts of the actual object. In particular, if a part has a class-wide type, the tag of the object might need to be examined in order to determine if build-in-place is required. However, we expect that most Ada implementations will determine this property at compile-time using some assume-the-worst algorithm in order to chose the appropriate method to implement a given call or aggregate. In addition, there is no attribute or other method for a program to determine if a particular object has this property (or not), so there is no value to a more careful description of this rule.

- In the case of an aggregate, if the full type of any part of the newly-created object is controlled, the anonymous object is built in place.

  Reason: \{AI05-0067-1\} This is necessary to prevent elaboration problems with deferred constants of controlled types.

   Consider:

     package P is
     type Dyn_String is private;
     Null_String : constant Dyn_String;
     ...
     private
     type Dyn_String is new Ada.Finalization.Controlled with ...
     procedure Finalize(X : in out Dyn_String);
     procedure Adjust(X : in out Dyn_String);
     Null_String : constant Dyn_String :=
     (Ada.Finalization.Controlled with ...);
     ...
     end P;

     When Null_String is elaborated, the bodies of Finalize and Adjust clearly have not been elaborated. Without this rule, this declaration would necessarily raise Program Error (unless the permissions given below are used by the implementation).

Ramification: An aggregate with a controlled part used in the return expression of a simple return statement has to be built in place in the anonymous return object, as this is similar to an object declaration. (This is a change from Ada 95, but it is not an inconsistency as it only serves to restrict implementation choices.) But this only covers the aggregate; a separate anonymous return object can still be used unless it too is required to be built in place.

Similarly, an aggregate that has a controlled part but is not itself controlled and that is used to initialize an object also has to be built in place. This is also a change from Ada 95, but it is not an inconsistency as it only serves to restrict implementation choices. This avoids problems if a type like Dyn_String (in the example above) is used as a component in a type used as a deferred constant in package P.

- In other cases, it is unspecified whether the anonymous object is built in place.

  Reason: This is left unspecified so the implementation can use any appropriate criteria for determining when to build in place. That includes making the decision on a call-by-call basis. Reasonable programs will not care what decision is made here anyway.

\{AI05-0067-1\} Notwithstanding what this International Standard says elsewhere, if an object is built in place:

- Upon successful completion of the return statement or aggregate, the anonymous object mutates into the newly-created object; that is, the anonymous object ceases to exist, and the newly-created object appears in its place.

- Finalization is not performed on the anonymous object.

- Adjustment is not performed on the newly-created object.
• All access values that designate parts of the anonymous object now designate the corresponding parts of the newly-created object.

• All renamings of parts of the anonymous object now denote views of the corresponding parts of the newly-created object.

• Coextensions of the anonymous object become coextensions of the newly-created object.

To be honest: This “mutating” does not necessarily happen atomically with respect to abort and other tasks. For example, if a function call is used as the parent part of an extension_aggregate, then the tag of the anonymous object (the function result) will be different from the tag of the newly-created object (the parent part of the extension_aggregate). In implementation terms, this involves modifying the tag field. If the current task is aborted during this modification, the object might become abnormal. Likewise, if some other task accesses the tag field during this modification, it constitutes improper use of shared variables, and is erroneous.

Implementation Note: The intended implementation is that the anonymous object is allocated at the same address as the newly-created object. Thus, no run-time action is required to cause all the access values and renamings to point to the right place. They just point to the newly-created object, which is what the return object has magically “mutated into”.

There is no requirement that ‘Address of the return object is equal to ‘Address of the newly-created object, but that will be true in the intended implementation.

For a function call, if the size of the newly-created object is known at the call site, the object is allocated there, and the address is implicitly passed to the function; the return object is created at that address. Otherwise, a storage pool is implicitly passed to the function; the size is determined at the point of the return statement, and passed to the Allocate procedure. The address returned by the storage pool is returned from the function, and the newly-created object uses that same address. If the return statement is left without returning (via an exception or a goto, for example), then Deallocation is called. The storage pool might be a dummy pool that represents “allocate on the stack”.

The Tag of the newly-created object may be different from that of the result object. Likewise, the master and accessibility level may be different.

An alternative implementation model might allow objects to move around to different addresses. In this case, access values and renamings would need to be modified at run time. It seems that this model requires the full power of tracing garbage collection.

Implementation Requirements

For an aggregate of a controlled type whose value is assigned, other than by an assignment_statement or a return_statement, the implementation shall not create a separate anonymous object for the aggregate. The aggregate value shall be constructed directly in the target of the assignment operation and Adjust is not called on the target object.

Reason: This build-in-place requirement is necessary to prevent elaboration problems with deferred constants of controlled types. Consider:

```ada
package P is
  type Dyn_String is private;
  Null_String : constant Dyn_String := (Ada.Finalization.Controlled with ...);
  procedure Finalize(X : in out Dyn_String);
  procedure Adjust(X : in out Dyn_String);

  procedure Finalize(X : in out Dyn_String);
  procedure Adjust(X : in out Dyn_String);

  Null_String : constant Dyn_String := (Ada.Finalization.Controlled with ...);
end P;
```

When Null_String is elaborated, the bodies of Finalize and Adjust clearly have not been elaborated. Without this rule, this declaration would necessarily raise Program_Error (unless the permissions given below are used by the implementation).

Ramification: An aggregate of a controlled type used in the return expression of a simple return_statement has to be built-in-place in the anonymous return object, as this is similar to an object declaration. (This is a change from Ada 95, but it is not an inconsistency as it only serves to restrict implementation choices.) But this only covers the aggregate; a separate anonymous return object can still be used unless it too is required to be built-in-place (see 7.5).
Implementation Permissions

{AI05-0067-1} An implementation is allowed to relax the above rules for assignment_statement (for nonlimited controlled types) in the following ways:

This paragraph was deleted. Proof: {AI05-0067-1} The phrase “for nonlimited controlled types” follows from the fact that all of the following permissions apply to cases involving assignment. It is important because the programmer can count on a stricter semantics for limited controlled types.

Ramification: {AI05-0067-1} The relaxations apply only to nonlimited types, as assignment statements are not allowed for limited types. This is important so that the programmer can count on a stricter semantics for limited controlled types.

{AI05-0067-1} If an assignment_statement that assigns to an object is assigned the value of that same object, the implementation need not do anything.

Ramification: In other words, even if an object is controlled and a combination of Finalize and Adjust on the object might have a net side effect, they need not be performed.

{AI05-0067-1} For assignment_statement, the implementation may finalize and assign each component of the variable separately (rather than finalizing the entire variable and assigning the entire new value) unless a discriminant of the variable is changed by the assignment.

Reason: For example, in a slice assignment, an anonymous object is not necessary if the slice is copied component-by-component in the right direction, since array types are not controlled (although their components may be). Note that the direction, and even the fact that it's a slice assignment, can in general be determined only at run time.

Ramification: {AI05-0005-1} This potentially breaks a single assignment operation into many, and thus abort deferral (see 9.8) needs to last only across an individual component assignment when the component has a controlled part. It is only important that the copy step is not separated (by an abort) from the adjust step, so aborts between component assignments is not harmful.

For an aggregate or function call whose value is assigned into a target object, the implementation need not create a separate anonymous object if it can safely create the value of the aggregate of function call directly in the target object. Similarly, for an assignment_statement, the implementation need not create an anonymous object if the value being assigned is the result of evaluating a name denoting an object (the source object) whose storage cannot overlap with the target. If the source object might overlap with the target object, then the implementation can avoid the need for an intermediary anonymous object by exercising one of the above permissions and perform the assignment one component at a time (for an overlapping array assignment), or not at all (for an assignment where the target and the source of the assignment are the same object). Even if an anonymous object is created, the implementation may move its value to the target object as part of the assignment without re-adjusting so long as the anonymous object has no aliased subcomponents.

Reason: {AI05-0005-1} If the anonymous object is eliminated by this permission, in the aggregate case, only one value adjustment is necessary, and there is no anonymous object to be finalized and thus the Finalize call on it is eliminated.

Note that if the anonymous object is eliminated but the new value is not built in place in the target object, similarly in the function call case, the anonymous object can be eliminated. Note, however, that Adjust must be called on the assignment_statement case as well, no finalization of the anonymous object is needed. On the other hand, if the target has aliased subcomponents, then an adjustment takes place directly on the target object as the last step of the assignment, since some of the subcomponents may be self-referential or otherwise position-dependent. This Adjust can be eliminated only by using one of the following permissions.

Furthermore, an implementation is permitted to omit implicit Initialize, Adjust, and Finalize calls and associated assignment operations on an object of a nonlimited controlled type provided that:

- any omitted Initialize call is not a call on a user-defined Initialize procedure, and

To be honest: This does not apply to any calls to a user-defined Initialize routine that happen to occur in an Adjust or Finalize routine. It is intended that it is never necessary to look inside of an Adjust or Finalize routine to determine if the call can be omitted.
Reason: We don't want to eliminate objects for which the Initialize might have side effects (such as locking a resource).

- any usage of the value of the object after the implicit Initialize or Adjust call and before any subsequent Finalize call on the object does not change the external effect of the program, and

- after the omission of such calls and operations, any execution of the program that executes an Initialize or Adjust call on an object or initializes an object by an aggregate will also later execute a Finalize call on the object and will always do so prior to assigning a new value to the object, and

- the assignment operations associated with omitted Adjust calls are also omitted.

This permission applies to Adjust and Finalize calls even if the implicit calls have additional external effects.

Reason: The goal of the above permissions is to allow typical dead assignment and dead variable removal algorithms to work for nonlimited controlled types. We require that "pairs" of Initialize/Adjust/Finalize operations are removed. (These aren't always pairs, which is why we talk about "any execution of the program".)

Extensions to Ada 83

Controlled types and user-defined finalization are new to Ada 95. (Ada 83 had finalization semantics only for masters of tasks.)

Extensions to Ada 95

{AI95-00161-01} Amendment Correction: Types Controlled and Limited_Controlled now have Preelaborable_Initialization, so that objects of types derived from these types can be used in preelaborated packages.

Wording Changes from Ada 95

{8652/0020} {AI95-00126-01} Corrigendum: Clarified that Ada_Finalization is a remote types package.

{8652/0021} {AI95-00182-01} Corrigendum: Added wording to clarify that the default initialization (whatever it is) of an ancestor part is used.

{8652/0022} {AI95-00083-01} Corrigendum: Clarified that Adjust is never called on an aggregate used for the initialization of an object or subaggregate, or passed as a parameter.

{AI95-00147-01} Additional optimizations are allowed for nonlimited controlled types. These allow traditional dead variable elimination to be applied to such types.

{AI95-00318-02} Corrected the build-in-place requirement for controlled aggregates to be consistent with the requirements for limited types.

{AI95-00348-01} The operations of types Controlled and Limited_Controlled are now declared as null procedures (see 6.7) to make the semantics clear (and to provide a good example of what null procedures can be used for).

{AI95-00360-01} Types that need finalization are defined; this is used by the No_Nested_Finalization restriction (see D.7, “Tasking Restrictions”).

{AI95-00373-01} Generalized the description of objects that have Initialize called for them to say that it is done for all objects that are initialized by default. This is needed so that all of the new cases are covered.

Extensions to Ada 2005

{AI05-0212-1} Package Ada_Finalization now has Pure categorization, so it can be mentioned for any package. Note that this does not change the preelaborability of objects descended from Controlled and Limited_Controlled.

Wording Changes from Ada 2005

{AI05-0013-1} Correction: Eliminated coextensions from the “needs finalization” rules, as this cannot be determined in general in the compilation unit that declares the type. (The designated type of the coextension may have been imported as a limited view.) Uses of “needs finalization” need to ensure that coextensions are handled by other means (such as in No_Nested_Finalization – see D.7) or that coextensions cannot happen.

{AI05-0013-1} Correction: Corrected the “needs finalization” rules to include class-wide types, as a future extension can include a part that needs finalization.

{AI05-0026-1} Correction: Corrected the “needs finalization” rules to clearly say that they ignore privacy.
7.6.1 Completion and Finalization

This subclause defines completion and leaving of the execution of constructs and entities. A master is the execution of a construct that includes finalization of local objects after it is complete (and after waiting for any local tasks — see 9.3), but before leaving. Other constructs and entities are left immediately upon completion.

Dynamic Semantics

2/2 \{AI95-00318-02\} The execution of a construct or entity is complete when the end of that execution has been reached, or when a transfer of control (see 5.1) causes it to be abandoned. Completion due to reaching the end of execution, or due to the transfer of control of an exit_statement, return_statement, goto_statement, exit_statement, return_statement, goto_statement, or requeue_statement or of the selection of a terminate_alternative is normal completion. Completion is abnormal otherwise — when control is transferred out of a construct due to abort or the raising of an exception.

Discussion: Don't confuse the run-time concept of completion with the compile-time concept of completion defined in 3.11.1.

3/2 \{AI95-00162-01\} \{AI95-00416-01\} After execution of a construct or entity is complete, it is left, meaning that execution continues with the next action, as defined for the execution that is taking place. Leaving an execution happens immediately after its completion, except in the case of a master: the execution of a body other than a package_body; the execution of a statement; or the evaluation of an expression, function_call, or range that is not part of an enclosing expression, function_call, range, or simple_statement other than a simple_return_statement, task_body, a block_statement, a subprogram_body, an entry_body, or an accept_statement. A master is finalized after it is complete, and before it is left.

Reason: \{AI95-00162-01\} \{AI95-00416-01\} Expressions and statements are masters so that objects created by subprogram calls (in aggregates, allocators for anonymous access-to-object types, and so on) are finalized and have their tasks awaited before the expressions or statements are left. Note that expressions like the condition of an if_statement are masters, because they are not enclosed by a simple_statement. Similarly, a function_call which is renamed is a master, as it is not in a simple_statement.

3.2/2 \{AI95-00416-01\} We have to include function_calls in the contexts that do not cause masters to occur so that expressions contained in a function_call (that is not part of an expression or simple_statement) do not individually become masters. We certainly do not want the parameter expressions of a function_call to be separate masters, as they would then be finalized before the function is called.

Ramification: \{AI95-00416-01\} The fact that a function_call is a master does not change the accessibility of the return object denoted by the function_call, that depends on the use of the function_call. The function_call is the master of any short-lived entities (such as aggregates used as parameters of types with task or controlled parts).

4 For the finalization of a master, dependent tasks are first awaited, as explained in 9.3. Then each object whose accessibility level is the same as that of the master is finalized if the object was successfully initialized and still exists. [These actions are performed whether the master is left by reaching the last statement or via a transfer of control.] When a transfer of control causes completion of an execution, each included master is finalized in order, from innermost outward.

4.a Ramification: As explained in 3.10.2, the set of objects with the same accessibility level as that of the master includes objects declared immediately within the master, objects declared in nested packages, objects created by allocators (if the ultimate ancestor access type is declared in one of those places) and subcomponents of all of these things. If an object was already finalized by Unchecked_Deallocation, then it is not finalized again when the master is left.
After the finalization of a master is complete, the rule is applied as though each such object that still exists; the object will still exist when the corresponding master completes, and it will be finalized then.

To be honest: Subcomponents of objects due to be finalized are not finalized by the finalization of the master; they are finalized by the finalization of the containing object.

Reason: We need to finalize subcomponents of objects even if the containing object is not going to get finalized because it was not fully initialized. But if the containing object is finalized, we don't want to require repeated finalization of the subcomponents, as might normally be implied by the recursion in finalization of a master and the recursion in finalization of an object.

To be honest: Formally, completion and leaving refer to executions of constructs or entities. However, the standard sometimes (informally) refers to the constructs or entities whose executions are being completed. Thus, for example, “the subprogram call or task is complete” really means “the execution of the subprogram call or task is complete.”

For the finalization of an object:

- **{AI95-0099-1}** If the full type of the object is of an elementary type, finalization has no effect;

  **Reason:** {AI05-0099-1} We say “full type” in this and the following bullets as privacy is ignored for the purpose of determining the finalization actions of an object; that is as expected for Dynamic Semantics rules.

- **{AI95-0099-1}** If the full type of the object is a tagged type, and the tag of the object identifies of a controlled type, the Finalize procedure of that controlled type is called;

- **{AI95-0099-1}** If the full type of the object is of a protected type, or if the full type of the object is a tagged type and the tag of the object identifies a protected type, the actions defined in 9.4 are performed;

- **{AI95-00416-01}** {AI05-0099-1} If the full type of the object is of a composite type, then after performing the above actions, if any, every component of the object is finalized in an arbitrary order, except as follows: if the object has a component with an access discriminant constrained by a per-object expression, this component is finalized before any components that do not have such discriminants; for an object with several components with such a discriminant, they are finalized in the reverse of the order of their component Declarations;

  **Reason:** This allows the finalization of a component with an access discriminant to refer to other components of the enclosing object prior to their being finalized.

  **To be honest:** {AI05-0099-1} The components discussed here are all of the components that the object actually has, not just those components that are statically identified by the type of the object. These can be different if the object has a classwide type.

- **{AI95-00416-01}** If the object has coextensions (see 3.10.2), each coextension is finalized after the object whose access discriminant designates it.

  **Ramification:** {AI05-0066-1} In the case of an aggregate or function call that is used (in its entirety) to directly initialize a part of an object, the coextensions of the result of evaluating the aggregate or function call are transferred to become coextensions of the object being initialized and are not finalized until the object being initialized is ultimately finalized, even if an anonymous object is created as part of the operation.

Immediately before an instance of Unchecked_Deallocation reclaims the storage of an object, the object is finalized. [If an instance of Unchecked_Deallocation is never applied to an object created by an allocator, the object will still exist when the corresponding master completes, and it will be finalized then.]

{AI95-00280-01} {AI05-0051-1} {AI05-0190-1} The order in which the finalization of a master performs finalization of objects is as follows: Objects created by declarations in the master are finalized in the reverse order of their creation. For objects that were created by allocators for an access type whose ultimate ancestor is declared in the master, this rule is applied as though each such object that still exists had been created in an arbitrary order at the first freezing point (see 13.14) of the ultimate ancestor type; the finalization of these objects is called the finalization of the collection. Objects created by allocators for an anonymous access type that are not coextensions of some other object, are finalized in an arbitrary order during the finalization of their associated master. **After the finalization of a master is complete, the**
objects finalized as part of its finalization cease to exist, as do any types and subtypes defined and created within the master.

This paragraph was deleted. **Reason:** [AI05-0190-1] Note that we talk about the type of the allocator here. There may be access values of a (general) access type pointing at objects created by allocators for some other type; these are not finalized at this point.

This paragraph was deleted. **Reason:** [AI05-0190-1] The freezing point of the ultimate ancestor access type is chosen because before that point, pool elements cannot be created, and after that point, access values designating (parts of) the pool elements can be created. This is also the point after which the pool object cannot have been declared. We don’t want to finalize the pool elements until after anything finalizing objects that contain access values designating them. Nor do we want to finalize pool elements after finalizing the pool object itself.

This paragraph was deleted. **Ramification:** [AI05-0190-1] Finalization of allocated objects is done according to the (ultimate ancestor) allocator type, not according to the storage pool in which they are allocated. Pool finalization might reclaim storage (see 13.11, “Storage Management”), but has nothing (directly) to do with finalization of the pool elements.

This paragraph was deleted. **Reason:** [AI05-0190-1] Note that finalization is done only for objects that still exist; if an instance of Unchecked_Deallocation has already gotten rid of a given pool element, that pool element will not be finalized when the master is left.

Note that a deferred constant declaration does not create the constant; the full constant declaration creates it. Therefore, the order of finalization depends on where the full constant declaration occurs, not the deferred constant declaration.

An imported object is not created by its declaration. It is neither initialized nor finalized.

**Implementation Note:** An implementation has to ensure that the storage for an object is not reclaimed when references to the object are still possible (unless, of course, the user explicitly requests reclamation via an instance of Unchecked_Deallocation). This implies, in general, that objects cannot be deallocated one by one as they are finalized; a subsequent finalization might reference an object that has been finalized, and that object had better be in its (well-defined) finalized state.

**AI05-0190-1** Each nonderived access type \( T \) has an associated **collection**, which is the set of objects created by allocators of \( T \), or of types derived from \( T \). Unchecked_Deallocation removes an object from its collection. Finalization of a collection consists of finalization of each object in the collection, in an arbitrary order. The collection of an access type is an object implicitly declared at the following place:

**Ramification:** [AI05-0190-1] The place of the implicit declaration determines when allocated objects are finalized. For multiple collections declared at the same place, we do not define the order of their implicit declarations.

[AI05-0190-1] Finalization of allocated objects is done according to the (ultimate ancestor) allocator type, not according to the storage pool in which they are allocated. Pool finalization might reclaim storage (see 13.11, “Storage Management”), but has nothing (directly) to do with finalization of the pool elements.

[AI05-0190-1] Note that finalization is done only for objects that still exist; if an instance of Unchecked_Deallocation has already gotten rid of a given pool element, that pool element will not be finalized when the master is left.

**Reason:** [AI05-0190-1] Note that we talk about the type of the allocator here. There may be access values of a (general) access type pointing at objects created by allocators for some other type; these are not (necessarily) finalized at this point.

- For a named access type, the first freezing point (see 13.14) of the type.

**Reason:** [AI05-0190-1] The freezing point of the ultimate ancestor access type is chosen because before that point, pool elements cannot be created, and after that point, access values designating (parts of) the pool elements can be created. This is also the point after which the pool object cannot have been declared. We don’t want to finalize the pool elements until after anything finalizing objects that contain access values designating them. Nor do we want to finalize pool elements after finalizing the pool object itself.

- For the type of an access parameter, the call that contains the allocator.

- For the type of an access result, within the master of the call (see 3.10.2).

**To be honest:** [AI05-0005-1] [AI05-0190-1] We mean at a place within the master consistent with the execution of the call within the master. We don’t say that normatively, as it is difficult to explain that when the master of the call need not be the master that immediately includes the call (such as when an anonymous result is converted to a named access type).

- For any other anonymous access type, the first freezing point of the innermost enclosing declaration.
The target of an assignment statement is finalized before copying in the new value, as explained in 7.6.

The master of an object is the master enclosing its creation whose accessibility level (see 3.10.2) is equal to that of the object, except in the case of an anonymous object representing the result of an aggregate or function call. If such an anonymous object is part of the result of evaluating the actual parameter expression for an explicitly aliased parameter of a function call, the master of the object is the innermost master enclosing the evaluation of the aggregate or function call, excluding the aggregate or function call itself. Otherwise, the master of such an anonymous object is the innermost master enclosing the evaluation of the aggregate or function call, which may be the aggregate or function call itself.

This paragraph was deleted. To be honest, this is not to be construed as permission to call Finalize asynchronously with respect to normal user code. For example:

```ada
declare
    X : Some_Controlled_Type := F(G(....));
begin
    -- The anonymous objects created for F and G are finalized no later than this point.
    -- Y := ...
    begin...
        -- The anonymous object for G should not be finalized at some random point in the middle of the body of F, because F might manipulate the same data structures as the Finalize operation, resulting in erroneous access to shared variables.
    end...
end;
```

Reason: This effectively imports all of the special rules for the accessibility level of renames, allocators, and so on, and applies them to determine where objects created in them are finalized. For instance, the master of a rename of a subprogram is that of the renamed subprogram. It might be quite inconvenient for the implementation to defer finalization of the anonymous object for G until after copying the value of F into X, especially if the size of the result is not known at the call site.

In 3.10.2 we assign an accessibility level to the result of an aggregate or function call that is used to directly initialize a part of an object based on the object being initialized. This is important to ensure that any access discriminants denote objects that live at least as long as the object being initialized. However, if the result of the aggregate or function call is not built directly in the target object, but instead is built in an anonymous object that is then assigned to the target, the anonymous object needs to be finalized after the assignment rather than persisting until the target object is finalized (but not its coextensions). (Note that an implementation is never required to create such an anonymous object, and in some cases is required to not have such a separate object, but rather to build the result directly in the target.)

The special case for explicitly aliased parameters of functions is needed for the same reason, as access discriminants of the returned object may designate one of these parameters. In that case, we want to lengthen the lifetime of the anonymous objects as long as the possible lifetime of the result.

We don't do a similar change for other kinds of calls, because the extended lifetime of the parameters adds no value, but could constitute a storage leak. For instance, such an anonymous object created by a procedure call in the elaboration part of a package body would have to live until the end of the program, even though it could not be used after the procedure returns (other than via Unchecked_Access).

Ramification: Note that the lifetime of the master given to anonymous objects in explicitly aliased parameters of functions is not necessarily as long as the lifetime of the master of the object being initialized (if the function call is used to initialize an allocator, for instance). In that case, the accessibility check on explicitly aliased parameters will necessarily fail if any such anonymous objects exist. This is necessary to avoid requiring the objects to live as long as the access type or having the implementation complexity of an implicit coextension.
In the case of an expression that is a master, finalization of any (anonymous) objects occurs after completing the final part of evaluation of the expression and all use of the objects, prior to starting the execution of any subsequent construct. If a transfer of control or raising of an exception occurs prior to performing a finalization of an anonymous object, the anonymous object is finalized as part of the finalizations due to be performed for the object's innermost enclosing master.

Bounded (Run-Time) Errors

It is a bounded error for a call on Finalize or Adjust that occurs as part of object finalization or assignment to propagate an exception. The possible consequences depend on what action invoked the Finalize or Adjust operation:

• For a Finalize invoked as part of an assignment_statement, Program_Error is raised at that point.

For an Adjust invoked as part of assignment operations other than those invoked as part of an assignment_statement, the initialization of a controlled_object, other adjustments due to be performed might or might not be performed, and then Program_Error is raised. During its propagation, finalization might or might not be applied to objects whose Adjust failed. For an Adjust invoked as part of an assignment_statement, any other adjustments due to be performed are performed, and then Program_Error is raised.

Reason: In the case of assignments that are part of initialization, there is no need to complete all adjustments if one propagates an exception, as the object will immediately be finalized. So long as a subcomponent is not going to be finalized, it need not be adjusted, even if it is initialized as part of an enclosing composite assignment operation for which some adjustments are performed. However, there is no harm in an implementation making additional Adjust calls (as long as any additional components that are adjusted are also finalized), so we allow the implementation flexibility here. On the other hand, for an assignment_statement, it is important that all adjustments be performed, even if one fails, because all controlled subcomponents are going to be finalized. Other kinds of assignment are more like initialization than assignment_statements, so we include them as well in the permission.

Ramification: Even if an Adjust invoked as part of the initialization of a controlled object propagates an exception, objects whose initialization (including any Adjust or Initialize calls) successfully completed will be finalized. The permission above only applies to objects whose Adjust failed. Objects for which Adjust was never even invoked must not be finalized.

For a Finalize invoked as part of a call on an instance of Unchecked_Deallocation, any other finalizations due to be performed are performed, and then Program_Error is raised.

This rule covers both ordinary objects created by a declaration, and anonymous objects created as part of evaluating an expression. All contexts that create objects that need finalization are defined to be masters.
• \{AI95-00318-02\} For a Finalize invoked by the transfer of control of an exit_statement, return_statement, goto_statement, exit_statement, return_statement, goto_statement, or requeue_statement, Program_Error is raised no earlier than after the finalization of the master being finalized when the exception occurred, and no later than the point where normal execution would have continued. Any other finalizations due to be performed up to that point are performed before raising Program_Error.

**Ramification:** For example, upon leaving a block_statement due to a goto_statement, the Program_Error would be raised at the point of the target statement denoted by the label, or else in some more dynamically nested place, but not so nested as to allow an exception_handler that has visibility upon the finalized object to handle it. For example,

```ada
procedure Main is
begin
   <<The_Label>>
   Outer_Block_Statement : declare
      X : Some_Controlled_Type;
   begin
      Inner_Block_Statement : declare
         Y : Some_Controlled_Type;
         Z : Some_Controlled_Type;
      begin
         goto The_Label;
         exception
            when Program_Error => ... -- Handler number 1.
         end;
      exception
         when Program_Error => ... -- Handler number 2.
      end;
      exception
         when Program_Error => ... -- Handler number 3.
   end;
end Main;
```

The goto_statement will first cause Finalize(Y) to be called. Suppose that Finalize(Y) propagates an exception. Program_Error will be raised after leaving Inner_Block_Statement, but before leaving Main. Thus, handler number 1 cannot handle this Program_Error; it will be handled either by handler number 2 or handler number 3. If it is handled by handler number 2, then Finalize(Z) will be done before executing the handler. If it is handled by handler number 3, then Finalize(Z) and Finalize(X) will both be done before executing the handler.

• For a Finalize invoked by a transfer of control that is due to raising an exception, any other finalizations due to be performed for the same master are performed; Program_Error is raised immediately after leaving the master.

**Ramification:** If, in the above example, the goto_statement were replaced by a raise_statement, then the Program_Error would be handled by handler number 2, and Finalize(Z) would be done before executing the handler.

**Reason:** We considered treating this case in the same way as the others, but that would render certain exception_handlers useless. For example, suppose the only exception_handler is one for others in the main subprogram. If some deeply nested call raises an exception, causing some Finalize operation to be called, which then raises an exception, then normal execution “would have continued” at the beginning of the exception_handler. Raising Program_Error at that point would cause that handler’s code to be skipped. One would need two nested exception_handlers to be sure of catching such cases!

On the other hand, the exception_handler for a given master should not be allowed to handle exceptions raised during finalization of that master.

• For a Finalize invoked by a transfer of control due to an abort or selection of a terminate alternative, the exception is ignored; any other finalizations due to be performed are performed.

**Ramification:** This case includes an asynchronous transfer of control.

**To be honest:** This violates the general principle that it is always possible for a bounded error to raise Program_Error (see 1.1.5, “Classification of Errors”).

**Implementation Permissions**

\{AI05-0107-1\} **If the execution of an allocator propagates an exception, any parts of the allocated object that were successfully initialized may be finalized as part of the finalization of the innermost master enclosing the allocator.**
Reason: This allows deallocating the memory for the allocated object at the innermost master, preventing a storage leak. Otherwise, the object would have to stay around until the finalization of the collection that it belongs to, which could be the entire life of the program if the associated access type is library level.

Ramification: This allows the finalization of such objects to occur later than they otherwise would, but still as part of the finalization of the same master. Accessibility rules in 13.11.4 ensure that it is the same master (usually that of the environment task).

Implementation Note: This permission is intended to allow the allocated objects to "belong" to the subpool objects and to allow those objects to be finalized at the time that the storage pool is finalized (if they are not finalized earlier). This is expected to ease implementation, as the objects will only need to belong to the subpool and not also to the collection.

Reason: A user-written Finalize procedure should be idempotent since it can be called explicitly by a client (at least if the type is "visibly" controlled). Also, Finalize is used implicitly as part of the assignment_statement if the type is nonlimited, and an abort is permitted to disrupt an assignment_statement between finalizing the left-hand side and assigning the new value to it (an abort is not permitted to disrupt an assignment operation between copying in the new value and adjusting it).

Discussion: Or equivalently, a Finalize procedure should be “idempotent”; applying it twice to the same object should be equivalent to applying it once.

Reason: A user-written Finalize procedure should be idempotent since it can be called explicitly by a client (at least if the type is "visibly" controlled). Also, Finalize is used implicitly as part of the assignment_statement if the type is nonlimited, and an abort is permitted to disrupt an assignment_statement between finalizing the left-hand side and assigning the new value to it (an abort is not permitted to disrupt an assignment operation between copying in the new value and adjusting it).

Discussion: Either Initialize or Adjust, but not both, is applied to (almost) every controlled object when it is created: Initialize is done when no initial value is assigned to the object, whereas Adjust is done as part of assigning the initial value. The one exception is the anonymous object initialized by an aggregate (both the anonymous object created for an aggregate, or an object initialized by an aggregate that is built-in-place); Initialize is not applied to the aggregate as a whole, nor is the value of the aggregate or object adjusted.

All of the following use the assignment operation, and thus perform value adjustment:

- the assignment_statement (see 5.2);
- explicit initialization of a stand-alone object (see 3.3.1) or of a pool element (see 4.8);
- default initialization of a component of a stand-alone object or pool element (in this case, the value of each component is assigned, and therefore adjusted, but the value of the object as a whole is not adjusted);
- function return, when the result is not built-in-place: type is not a return-by-reference type (see 6.5); (adjustment of the result happens before finalization of the function; values of return-by-reference types are not adjusted);
- predefined operators (although the only one that matters is concatenation; see 4.5.3);
- generic formal objects of mode in (see 12.4); these are defined in terms of constant declarations; and
- aggregates (see 4.3), when the result is not built-in-place (in this case, the value of each component, and the parent part, for an extension_aggregate, is assigned, and therefore adjusted, but the value of the aggregate as a whole is not adjusted; neither is Initialize called);
The following also use the assignment operation, but adjustment never does anything interesting in these cases:

- By-copy parameter passing uses the assignment operation (see 6.4.1), but controlled objects are always passed by reference, so the assignment operation never does anything interesting in this case. If we were to allow by-copy parameter passing for controlled objects, we would need to make sure that the actual is finalized before doing the copy back for [in] out parameters. The finalization of the parameter itself needs to happen after the copy back (if any), similar to the finalization of an anonymous function return object or aggregate object.

- **For** loops use the assignment operation (see 5.5), but since the type of the loop parameter is never controlled, nothing interesting happens there, either.

| [AI95-00318-02] | Objects initialized by function results and aggregates that are built-in-place. In this case, the assignment operation is never executed, and no adjustment takes place. While built-in-place is always allowed, it is required for some types — see 7.5 and 7.6 — and that's important since limited types have no Adjust to call. |
|---------------------------------------------------------------|

This paragraph was deleted. | [AI95-00287-01] Because Controlled and Limited-Controlled are library level tagged types, all controlled types will be library level types, because of the accessibility rules (see 3.10.2 and 3.9.1). This ensures that the Finalize operations may be applied without providing any “display” or “static link.” This simplifies Finalization as a result of garbage collection, abort, and asynchronous transfer of control. |

Finalization of the parts of a protected object are not done as protected actions. It is possible (in pathological cases) to create tasks during finalization that access these parts in parallel with the finalization itself. This is an erroneous use of shared variables.

**Implementation Note:** One implementation technique for finalization is to chain the controlled objects together on a per-task list. When leaving a master, the list can be walked up to a marked place. The links needed to implement the list can be declared (privately) in types Controlled and Limited-Controlled, so they will be inherited by all controlled types.

Another implementation technique, which we refer to as the “PC-map” approach essentially implies inserting exception handlers at various places, and finalizing objects based on where the exception was raised.

The PC-map approach is for the compiler/linker to create a map of code addresses; when an exception is raised, or abort occurs, the map can be consulted to see where the task was executing, and what finalization needs to be performed. This approach was given in the Ada 83 Rationale as a possible implementation strategy for exception handling — the map is consulted to determine which exception handler applies.

If the PC-map approach is used, the implementation must take care in the case of arrays. The generated code will generally contain a loop to initialize an array. If an exception is raised part way through the array, the components that have been initialized must be finalized, and the others must not be finalized.

It is our intention that both of these implementation methods should be possible.

**Wording Changes from Ada 83**

| [AI95-00299-1] | Finalization depends on the concepts of completion and leaving, and on the concept of a master. Therefore, we have moved the definitions of these concepts here, from where they used to be in Clause Section 9. These concepts also needed to be generalized somewhat. Task waiting is closely related to user-defined finalization; the rules here refer to the task-waiting rules of Clause Section 9. |

**Inconsistencies With Ada 95**

| [AI05-0066-1] | Ada 2012 Correction: Changed the definition of the master of an anonymous object used to directly initialize an object, so it can be finalized immediately rather than having to hang around as long as the object. In this case, the Ada 2005 definition was inconsistent with Ada 95, and Ada 2012 changes it back. It is unlikely that many compilers implemented the rule as written in Amendment 1, so an inconsistency is unlikely to arise in practice. |

**Wording Changes from Ada 95**

| [8652/0021] | [AI95-00182-01] **Corrigendum:** Fixed the wording to say that anonymous objects aren't finalized until the object can't be used anymore. |
| [8652/0023] | [AI95-00169-01] **Corrigendum:** Added wording to clarify what happens when Adjust or Finalize raises an exception; some cases had been omitted. |
| [8652/0024] | [AI95-00193-01] [AI95-00256-01] **Corrigendum:** Stated that if Adjust raises an exception during initialization, nothing further is required. This is corrected in Ada 2005 to include all kinds of assignment other than assignment statements.
Revised the definition of master to include expressions and statements, in order to cleanly define what happens for tasks and controlled objects created as part of a subprogram call. Having done that, all of the special wording to cover those cases is eliminated (at least until the Ada comments start rolling in).

We define finalization of the collection here, so as to be able to conveniently refer to it in other rules (especially in 4.8, “Allocators”).

Clarified that a coextension is finalized at the same time as the outer object. (This was intended for Ada 95, but since the concept did not have a name, it was overlooked.)

Inconsistencies With Ada 2005

Correction: Better defined when objects allocated from anonymous access types are finalized. This could be inconsistent if objects are finalized in a different order than in an Ada 2005 implementation and that order caused different program behavior; however programs that depend on the order of finalization within a single master are already fragile and hopefully are rare.

Wording Changes from Ada 2005

Correction: Removed a redundant rule, which is now covered by the additional places where masters are defined.

Correction: Clarified the finalization rules so that there is no doubt that privacy is ignored, and to ensure that objects of classwide interface types are finalized based on their specific concrete type.

Correction: Allowed premature finalization of parts of failed allocators. This could be an inconsistency, but the previous behavior is still allowed and there is no requirement that implementations take advantage of the permission.

Added a permission to finalize object allocated from a subpool later than usual.

Added text to specially define the master of anonymous objects which are passed as explicitly aliased parameters (see 6.1) of functions. The model for these parameters is explained in detail in 6.4.1.
8 Visibility Rules

{AI05-0299-1} [The rules defining the scope of declarations and the rules defining which identifiers, character_literals, and operator_symbols are visible at (or from) various places in the text of the program are described in this clause. The formulation of these rules uses the notion of a declarative region.

{AI05-0299-1} As explained in Clause Section 3, a declaration declares a view of an entity and associates a defining name with that view. The view comprises an identification of the viewed entity, and possibly additional properties. A usage name denotes a declaration. It also denotes the view declared by that declaration, and denotes the entity of that view. Thus, two different usage names might denote two different views of the same entity; in this case they denote the same entity.]

To be honest: In some cases, a usage name that denotes a declaration does not denote the view declared by that declaration, nor the entity of that view, but instead denotes a view of the current instance of the entity, and denotes the current instance of the entity. This sometimes happens when the usage name occurs inside the declarative region of the declaration.

Wording Changes from Ada 83

We no longer define the term “basic operation;” thus we no longer have to worry about the visibility of them. Since they were essentially always visible in Ada 83, this change has no effect. The reason for this change is that the definition in Ada 83 was confusing, and not quite correct, and we found it difficult to fix. For example, one wonders why an if_statement was not a basic operation of type Boolean. For another example, one wonders what it meant for a basic operation to be “inherent in” something. Finally, this fixes the problem addressed by AI83-00027/07.

8.1 Declarative Region

Static Semantics

For each of the following constructs, there is a portion of the program text called its declarative region, within which nested declarations can occur:

• any declaration, other than that of an enumeration type, that is not a completion [of a previous declaration];
• a block_statement;
• a loop_statement;
• {AI05-0255-1} a quantified_expression;
• {AI95-00318-02} an extended_return_statement;
• an accept_statement;
• an exception_handler.

The declarative region includes the text of the construct together with additional text determined recursively), as follows:

• If a declaration is included, so is its completion, if any.
• If the declaration of a library unit [including Standard — see 10.1.1] is included, so are the declarations of any child units [and their completions, by the previous rule]. The child declarations occur after the declaration.
• If a body_stub is included, so is the corresponding subunit.
• If a type_declaration is included, then so is a corresponding record_representation_clause, if any.

Reason: This is so that the component_declarations can be directly visible in the record_representation_clause.
The declarative region of a declaration is also called the *declarative region* of any view or entity declared by the declaration.

**Reason:** The constructs that have declarative regions are the constructs that can have declarations nested inside them. Nested declarations are declared in that declarative region. The one exception is for enumeration literals; although they are nested inside an enumeration type declaration, they behave as if they were declared at the same level as the type.

**To be honest:** A declarative region does not include *parent_unit_names*.

**Ramification:** A declarative region does not include *context_clauses*.

A declaration occurs *immediately within* a declarative region if this region is the innermost declarative region that encloses the declaration (the *immediately enclosing* declarative region), not counting the declarative region (if any) associated with the declaration itself.

**Discussion:** Don't confuse the declarative region of a declaration with the declarative region in which it immediately occurs.

[ A declaration is *local* to a declarative region if the declaration occurs immediately within the declarative region.] [An entity is *local* to a declarative region if the entity is declared by a declaration that is local to the declarative region.]

**Ramification:** "Occurs immediately within" and "local to" are synonyms (when referring to declarations).

Thus, "local to" applies to both declarations and entities, whereas "occurs immediately within" only applies to declarations. We use this term only informally; for cases where precision is required, we use the term "occurs immediately within", since it is less likely to cause confusion.

A declaration is *global* to a declarative region if the declaration occurs immediately within another declarative region that encloses the declarative region. An entity is *global* to a declarative region if the entity is declared by a declaration that is global to the declarative region.

NOTES

1. The children of a parent library unit are inside the parent's declarative region, even though they do not occur inside the parent's declaration or body. This implies that one can use (for example) "P.Q" to refer to a child of P whose defining name is Q, and that after "use P;" Q can refer (directly) to that child.

2. As explained above and in 10.1.1, “Compilation Units - Library Units”, all library units are descendants of Standard, and so are contained in the declarative region of Standard. They are *not* inside the declaration or body of Standard, but they *are* inside its declarative region.

3. For a declarative region that comes in multiple parts, the text of the declarative region does not contain any text that might appear between the parts. Thus, when a portion of a declarative region is said to extend from one place to another in the declarative region, the portion does not contain any text that might appear between the parts of the declarative region.

**Discussion:** It is necessary for the things that have a declarative region to include anything that contains declarations (except for enumeration type declarations). This includes any declaration that has a profile (that is, subprogram_declaration, subprogram_body, entry_declaration, subprogram_renaming_declaration, formal_subprogram_declaration, access-to-subprogram type_declaration), anything that has a discriminant_part (that is, various kinds of type_declaration), anything that has a component_list (that is, record type_declaration and record extension type_declaration), and finally the declarations of task and protected units and packages.

**Wording Changes from Ada 83**

It was necessary to extend Ada 83’s definition of declarative region to take the following Ada 95 features into account:

- Child library units.
- Derived types/type extensions — we need a declarative region for inherited components and also for new components.
- All the kinds of types that allow discriminants.
- Protected units.
- Entries that have bodies instead of accept statements.
- The choice_parameter_specification of an exception_handler.
- The formal parameters of access-to-subprogram types.
- Renamings-as-body.
Discriminated and access-to-subprogram type declarations need a declarative region. Enumeration type declarations cannot have one, because you don't have to say "Color.Red" to refer to the literal Red of Color. For other type declarations, it doesn't really matter whether or not there is an associated declarative region, so for simplicity, we give one to all types except enumeration types.

We now say that an accept_statement has its own declarative region, rather than being part of the declarative region of the entry_declaration, so that declarative regions are properly nested regions of text, so that it makes sense to talk about "inner declarative regions," and "...extends to the end of a declarative region." Inside an accept_statement, the name of one of the parameters denotes the parameter_specification of the accept_statement, not that of the entry_declaration. If the accept_statement is nested within a block_statement, these parameter_specifications can hide declarations of the block_statement. The semantics of such cases was unclear in RM83.

To be honest: Unfortunately, we have the same problem for the entry name itself — it should denote the accept_statement, but accept_statements are not declarations. They should be, and they should hide the entry from all visibility within themselves.

Note that we can't generalize this to entry_bodies, or other bodies, because the declarative_part of a body is not supposed to contain (explicit) homographs of things in the declaration. It works for accept_statements only because an accept_statement does not have a declarative_part.

To avoid confusion, we use the term “local to” only informally in Ada 95. Even RM83 used the term incorrectly (see, for example, RM83-12.3(13)).

In Ada 83, (root) library units were inside Standard; it was not clear whether the declaration or body of Standard was meant. In Ada 95, they are children of Standard, and so occur immediately within Standard's declarative region, but not within either the declaration or the body. (See RM83-8.6(2) and RM83-10.1.1(5).)

Wording Changes from Ada 95

{AI95-00318-02} Extended_return_statement (see 6.5) is added to the list of constructs that have a declarative region.

8.2 Scope of Declarations

[For each declaration, the language rules define a certain portion of the program text called the scope of the declaration. The scope of a declaration is also called the scope of any view or entity declared by the declaration. Within the scope of an entity, and only there, there are places where it is legal to refer to the declared entity. These places are defined by the rules of visibility and overloading.]

Static Semantics

The immediate scope of a declaration is a portion of the declarative region immediately enclosing the declaration. The immediate scope starts at the beginning of the declaration, except in the case of an overloadable declaration, in which case the immediate scope starts just after the place where the profile of the callable entity is determined (which is at the end of the _specification for the callable entity, or at the end of the generic_instantiation if an instance). The immediate scope extends to the end of the declarative region, with the following exceptions:

Reason: The reason for making overloadable declarations with profiles special is to simplify compilation: until the compiler has determined the profile, it doesn't know which other declarations are homographs of this one, so it doesn't know which ones this one should hide. Without this rule, two passes over the _specification or generic_instantiation would be required to resolve names that denote things with the same name as this one.

- The immediate scope of a library_item includes only its semantic dependents.

Reason: ClauseSection 10 defines only a partial ordering of library_items. Therefore, it is a good idea to restrict the immediate scope (and the scope, defined below) to semantic dependents.

Consider also examples like this:

```ada
package P is end P;
package P.Q is
    I : Integer := 0;
end P.Q;
```
with P;
package R is
  package X renames P;
  J : Integer := X.Q.I := 17; -- Illegal!
end R;

The scope of P.Q does not contain R. Hence, neither P.Q nor X.Q are visible within R. However, the name R.X.Q would be visible in some other library unit where both R and P.Q are visible (assuming R were made legal by removing the offending declaration).

Ramification: This rule applies to limited views as well as “normal” library items. In that case, the semantic dependents are the units that have a limited_with_clause for the limited view.

• The immediate scope of a declaration in the private part of a library unit does not include the visible part of any public descendant of that library unit.

Ramification: In other words, a declaration in the visible part can be visible within the visible part, private part and body of a private child unit. On the other hand, such a declaration can be visible within only the private part and body of a public child unit.

Reason: The purpose of this rule is to prevent children from giving private information to clients.

Ramification: For a public child subprogram, this means that the parent's private part is not visible in the profile formal_parts of the declaration and of the body. This is true even for subprogram_bodies that are not completions. For a public child generic unit, it means that the parent's private part is not visible in the generic_formal_part, as well as in the first list of basic_declarative_items (for a generic package), or the (syntactic) profile formal_parts (for a generic subprogram).

[The visible part of (a view of) an entity is a portion of the text of its declaration containing declarations that are visible from outside.] The private part of (a view of) an entity that has a visible part contains all declarations within the declaration of (the view of) the entity, except those in the visible part; [these are not visible from outside. Visible and private parts are defined only for these kinds of entities: callable entities, other program units, and composite types.]

• The visible part of a view of a callable entity is its profile.

• The visible part of a composite type other than a task or protected type consists of the declarations of all components declared [(explicitly or implicitly)] within the type_declaration.

• The visible part of a generic unit includes the generic_formal_part. For a generic package, it also includes the first list of basic_declarative_items of the package_specification. For a generic subprogram, it also includes the profile.

Reason: Although there is no way to reference anything but the formals from outside a generic unit, they are still in the visible part in the sense that the corresponding declarations in an instance can be referenced (at least in some cases). In other words, these declarations have an effect on the outside world. The visible part of a generic unit needs to be defined this way in order to properly support the rule that makes a parent's private part invisible within a public child's visible part.

Ramification: The visible part of an instance of a generic unit is as defined for packages and subprograms; it is not defined in terms of the visible part of a generic unit.

• [The visible part of a package, task unit, or protected unit consists of declarations in the program unit's declaration other than those following the reserved word private, if any; see 7.1 and 12.7 for packages, 9.1 for task units, and 9.4 for protected units.]

The scope of a declaration always contains the immediate scope of the declaration. In addition, for a given declaration that occurs immediately within the visible part of an outer declaration, or is a public child of an outer declaration, the scope of the given declaration extends to the end of the scope of the outer declaration, except that the scope of a library_item includes only its semantic dependents.

Ramification: Note the recursion. If a declaration appears in the visible part of a library unit, its scope extends to the end of the scope of the library unit, but since that only includes dependents of the declaration of the library unit, the scope of the inner declaration also only includes those dependents. If X renames library package P, which has a child Q, a with_clause mentioning P.Q is necessary to be able to refer to X.Q, even if P.Q is visible at the place where X is declared.
The scope of an attribute_definition_clause is identical to the scope of a declaration that would occur at the point of the attribute_definition_clause. The scope of an aspect_specification is identical to the scope of the associated declaration.

The immediate scope of a declaration is also the immediate scope of the entity or view declared by the declaration. Similarly, the scope of a declaration is also the scope of the entity or view declared by the declaration.

**Ramification:** The rule for immediate scope implies the following:

- If the declaration is that of a library unit, then the immediate scope includes the declarative region of the declaration itself, but not other places, unless they are within the scope of a with_clause that mentions the library unit.

It is necessary to attach the semantics of with_clauses to [immediate] scopes (as opposed to visibility), in order for various rules to work properly. A library unit should hide a homographic implicit declaration that appears in its parent, but only within the scope of a with_clause that mentions the library unit. Otherwise, we would violate the "legality determinable via semantic dependences" rule of 10, “Program Structure and Compilation Issues”. The declaration of a library unit should be allowed to be a homograph of an explicit declaration in its parent’s body, so long as that body does not mention the library unit in a with_clause.

This means that one cannot denote the declaration of the library unit, but one might still be able to denote the library unit via another view.

A with_clause does not make the declaration of a library unit visible; the lack of a with_clause prevents it from being visible. Even if a library unit is mentioned in a with_clause, its declaration can still be hidden.

- The completion of the declaration of a library unit (assuming that's also a declaration) is not visible, neither directly nor by selection, outside that completion.

- The immediate scope of a declaration immediately within the body of a library unit does not include any child of that library unit.

This is needed to prevent children from looking inside their parent's body. The children are in the declarative region of the parent, and they might be after the parent's body. Therefore, the scope of a declaration that occurs immediately within the body might include some children.

**NOTES**

4 {AI05-0299-1} There are notations for denoting visible declarations that are not directly visible. For example, parameter_specifications are in the visible part of a subprogram_declaration so that they can be used in named-notation calls appearing outside the called subprogram. For another example, declarations of the visible part of a package can be denoted by expanded names appearing outside the package, and can be made directly visible by a use_clause.

**Ramification:** {AI95-0014-01} {AI05-0299-1} There are some obscure cases involving generics cases in which there is no such notation. See Clause Section 12.

**Extensions to Ada 83**

The fact that the immediate scope of an overloadable declaration does not include its profile is new to Ada 95. It replaces RM83-8.3(16), which said that within a subprogram specification and within the formal part of an entry declaration or accept statement, all declarations with the same designator as the subprogram or entry were hidden from all visibility. The RM83-8.3(16) rule seemed to be overkill, and created both implementation difficulties and unnecessary semantic complexity.

**Wording Changes from Ada 83**

We no longer need to talk about the scope of notations, identifiers, character_literals, and operator_symbols.

2 The notion of "visible part" has been extended in Ada 95. The syntax of task and protected units now allows private parts, thus requiring us to be able to talk about the visible part as well. It was necessary to extend the concept to subprograms and to generic units, in order for the visibility rules related to child library units to work properly. It was necessary to define the concept separately for generic formal packages, since their visible part is slightly different from that of a normal package. Extending the concept to composite types made the definition of scope slightly simpler. We define visible part for some things elsewhere, since it makes a big difference to the user for those things. For composite types and subprograms, however, the concept is used only in arcane visibility rules, so we localize it to this subclause.

In Ada 83, the semantics of with_clauses was described in terms of visibility. It is now described in terms of [immediate] scope.

We have clarified that the following is illegal (where Q and R are library units):
8.2 Scope of Declarations

even though Q is declared in the declarative region of Standard, because R does not mention Q in a with_clause.

**Wording Changes from Ada 95**

{AI95-00408-01} The scope of an attribute_definition_clause is defined so that it can be used to define the visibility of such a clause, so that can be used by the stream attribute availability rules (see 13.13.2).

**Wording Changes from Ada 2005**

{AI05-0183-1} The scope of an aspect_specification is defined for similar reasons that it was defined for attribute_definition_clauses.

8.3 Visibility

[The visibility rules, given below, determine which declarations are visible and directly visible at each place within a program. The visibility rules apply to both explicit and implicit declarations.]

*Static Semantics*

A declaration is defined to be *directly visible* at places where a *name* consisting of only an *identifier* or *operator_symbol* is sufficient to denote the declaration; that is, no *selected_component* notation or special context (such as preceding => in a named association) is necessary to denote the declaration. A declaration is defined to be *visible* wherever it is directly visible, as well as at other places where some *name* (such as a *selected_component*) can denote the declaration.

The syntactic category *direct_name* is used to indicate contexts where direct visibility is required. The syntactic category *selector_name* is used to indicate contexts where visibility, but not direct visibility, is required.

There are two kinds of direct visibility: *immediate visibility* and *use-visibility*. A declaration is immediately visible at a place if it is directly visible because the place is within its immediate scope. A declaration is use-visible if it is directly visible because of a *use_clause* (see 8.4). Both conditions can apply.

A declaration can be *hidden*, either from direct visibility, or from all visibility, within certain parts of its scope. Where hidden from all visibility, it is not visible at all (neither using a *direct_name* nor a *selector_name*). Where hidden from direct visibility, only direct visibility is lost; visibility using a *selector_name* is still possible.

[Two or more declarations are *overloaded* if they all have the same defining name and there is a place where they are all directly visible.]

**Ramification:** Note that a *name* can have more than one possible interpretation even if it denotes a nonoverloadable entity. For example, if there are two functions F that return records, both containing a component called C, then the name F.C has two possible interpretations, even though component declarations are not overloadable.

The declarations of callable entities [(including enumeration literals)] are *overloadable*, meaning that overloading is allowed for them.

**Ramification:** A generic_declaration is not overloadable within its own *generic_formal_part*. This follows from the rules about when a *name* denotes a current instance. See A183-00286. This implies that within a *generic_formal_part*, outer declarations with the same defining name are hidden from direct visibility. It also implies that if a generic formal parameter has the same defining name as the generic itself, the formal parameter hides the generic from direct visibility.
Two declarations are *homographs* if they have the same defining name, and, if both are overloaddable, their profiles are type conformant. [An inner declaration hides any outer homograph from direct visibility.]

**Glossary entry:** An overriding operation is one that replaces an inherited primitive operation. Operations may be marked explicitly as overriding or not overriding.

{8652/0025} {AI95-00044-01} [Two homographs are not generally allowed immediately within the same declarative region unless one overrides the other (see Legality Rules below).] The only declarations that are overridable are the implicit declarations for predefined operators and inherited primitive subprograms.

A declaration overrides another homograph that occurs immediately within the same declarative region in the following cases:

- {8652/0025} {AI95-00044-01} **A declaration that is not overridable overrides one that is overridable** An explicit declaration overrides an implicit declaration of a primitive subprogram, [regardless of which declaration occurs first];
  
  **Ramification:** {8652/0025} {AI95-00044-01} And regardless of whether the nonoverridable explicit declaration is overloaddable or not. For example, *statement_identifier* identifiers are covered by this rule.

  The “regardless of which declaration occurs first” is there because the explicit declaration could be a primitive subprogram of a partial view, and then the full view might inherit a homograph. We are saying that the explicit one wins (within its scope), even though the implicit one comes later.

  If the overriding declaration is also a subprogram, then it is a primitive subprogram.

  As explained in 7.3.1, “Private Operations”, some inherited primitive subprograms are never declared. Such subprograms cannot be overridden, although they can be reached by dispatching calls in the case of a tagged type.

- **The implicit declaration of an inherited operator overrides that of a predefined operator;**
  
  **Ramification:** In a previous version of Ada 9X, we tried to avoid the notion of predefined operators, and say that they were inherited from some magical root type. However, this seemed like too much mechanism. Therefore, a type can have a predefined "+" as well as an inherited "+". The above rule says the inherited one wins.

  {AI95-00114-01} The “regardless of which declaration occurs first” applies here as well, in the case where derived_type_definition derives from a private type declared in the parent unit, and the full view of the parent type has additional predefined operators, as explained in 7.3.1, “Private Operations”. Those predefined operators can be overridden by inherited subprograms implicitly declared earlier.

- **An implicit declaration of an inherited subprogram overrides a previous implicit declaration of an inherited subprogram.**
  
  **{AI95-00251-01} If two or more homographs are implicitly declared at the same place:**

  - **{AI95-00251-01} If at least one is a subprogram that is neither a null procedure nor an abstract subprogram, and does not require overriding (see 3.9.3), then they override those that are null procedures, abstract subprograms, or require overriding. If more than one such homograph remains that is not thus overridden, then they are all hidden from all visibility.

  - **{AI95-00251-01} Otherwise (all are null procedures, abstract subprograms, or require overriding), then any null procedure overrides all abstract subprograms and all subprograms that require overriding; if more than one such homograph remains that is not thus overridden, then if they are all fully conformant with one another, one is chosen arbitrarily; if not, they are all hidden from all visibility.**

  **Discussion:** In the case where the implementation arbitrarily chooses one overrider from among a group of inherited subprograms, users should not be able to determine which member was chosen, as the set of inherited subprograms which are chosen from must be fully conformant. This rule is needed in order to allow

```ada
package Outer is
    package Pl is
        type Ifc1 is interface;
        procedure Null_Procedure (X : Ifc1) is null;
        procedure Abstract_Subp (X : Ifc1) is abstract;
    end Pl;
```

package P2 is
  type Ifc2 is interface;
  procedure Null_Procedure (X : Ifc2) is null;
  procedure Abstract_Subp (X : Ifc2) is abstract;
end P2;

package P1 is
  type Ifc1 is interface;
  procedure Null_Procedure (X : Ifc1) is null;
end P1;

type T is abstract new P1.Ifc1 and P2.Ifc2 with null record;
end Outer;

without requiring that T explicitly override any of its inherited operations.

Full conformance is required here, as we cannot allow the parameter names to differ. If they did differ, the routine which was selected for overriding could be determined by using named parameter notation in a call.

When the subprograms do not conform, we chose not to adopt the “use clause” rule which would make them all visible resulting in likely ambiguity. If we had used such a rule, any successful calls would be confusing; and the fact that there are no Beaujolais-like effect to worry about means we can consider other rules. The hidden-from-all-visibility homographs are still inherited by further derivations, which avoids order-of-declaration dependencies and other anomalies.

We have to be careful not to include arbitrary selection if the routines have real bodies. (This can happen in generics, see the example in the incompatibilities section below.) We don’t want the ability to successfully call routines where the body executed depends on the compiler or a phase of the moon.

But we can consider other rules. The hidden-from-all-visibility homographs are still inherited by further derivations, which avoids order-of-declaration dependencies and other anomalies.

We have to be careful to not include arbitrary selection if the routines have real bodies. (This can happen in generics, see the example in the incompatibilities section below.) We don’t want the ability to successfully call routines where the body executed depends on the compiler or a phase of the moon.

Note that if the type is concrete, abstract subprograms are inherited as subprograms that require overriding. We include functions that require overriding as well; these don’t have real bodies, so they can use the more liberal rules.

[For an implicit declaration of a primitive subprogram in a generic unit, there is a copy of this declaration in an instance.] However, a whole new set of primitive subprograms is implicitly declared for each type declared within the visible part of the instance. These new declarations occur immediately after the type declaration, and override the copied ones. [The copied ones can be called only from within the instance; the new ones can be called only from outside the instance, although for tagged types, the body of a new one can be executed by a call to an old one.]

Discussion: In addition, this is also stated redundantly (again), and is repeated, in 12.3, “Generic Instantiation”. The rationale for the rule is explained there.

To be honest: The implicit subprograms declared when an operation of a progenitor is implemented by an entry or subprogram also override the appropriate implicitly declared inherited operations of the progenitor.

A declaration is visible within its scope, except where hidden from all visibility, as follows:

• An overridden declaration is hidden from all visibility within the scope of the overriding declaration.

Ramification: We have to talk about the scope of the overriding declaration, not its visibility, because it hides even when it is itself hidden.

Note that the scope of an explicit subprogram_declaration does not start until after its profile.

• A declaration is hidden from all visibility until the end of the declaration, except:

  • For a record type or record extension, the declaration is hidden from all visibility only until the reserved word record;

  • {AI95-00345-01} {AI05-0177-1} For a package_declaration, task_declaration, protected declaration, generic_package_declaration, or subprogram_body, or expression_function_declaration, the declaration is hidden from all visibility only until the reserved word is of the declaration.

Ramification: We’re talking about the is of the construct itself, here, not some random is that might appear in a generic_formal_part.

• {AI95-00345-01} For a task_declaration or protected declaration, the declaration is hidden from all visibility only until the reserved word with of the declaration if there is one, or the reserved word is of the declaration if there is no with.

To be honest: If there is neither a with nor is, then the exception does not apply and the name is hidden from all visibility until the end of the declaration. This oddity was inherited from Ada 95.
Reason: We need the “with or is” rule so that the visibility within an interface list does not vary by construct. That would make it harder to complete private extensions and would complicate implementations.

- If the completion of a declaration is a declaration, then within the scope of the completion, the first declaration is hidden from all visibility. Similarly, a discriminant_specification or parameter_specification is hidden within the scope of a corresponding discriminant_specification or parameter_specification of a corresponding completion, or of a corresponding accept_statement.

Ramification: This rule means, for example, that within the scope of a full_type_declaration that completes a private_type_declaration, the name of the type will denote the full_type_declaration, and therefore the full view of the type. On the other hand, if the completion is not a declaration, then it doesn't hide anything, and you can't denote it.

- \{AI95-00217-06\} \{AI95-00412-01\} The declaration of a library unit (including a library_unit_renaming_declaration) is hidden from all visibility except at places outside that are within its declarative region that are not within the scope of a nonlimited_with_clause with a clause that mentions it. The limited view of a library package is hidden from all visibility at places that are not within the scope of a limited_with_clause that mentions it; in addition, the limited view is hidden from all visibility within the declarative region of the package, as well as within the scope of any nonlimited_with_clause that mentions the package. Where the declaration of the limited view of a package is visible, any name that denotes the package denotes the limited view, including those provided by a package renaming. [For each declaration or renaming of a generic unit as a child of some parent generic package, there is a corresponding declaration nested immediately within each instance of the parent.] Such a nested declaration is hidden from all visibility except at places that are within the scope of a with_clause that mentions the child.

Discussion: \{AI95-00217-06\} This is the rule that prevents with_clauses from being transitive; the [immediate] scope includes indirect semantic dependents. This rule also prevents the limited view of a package from being visible in the same place as the full view of the package, which prevents various ripple effects.

- \{AI95-00217-06\} \{AI95-00412-01\} [For each declaration or renaming of a generic unit as a child of some parent generic package, there is a corresponding declaration nested immediately within each instance of the parent.] Such a nested declaration is hidden from all visibility except at places that are within the scope of a with_clause that mentions the child.

A declaration with a defining_identifier or defining_operator_symbol is immediately visible [(and hence directly visible)] within its immediate scope except where hidden from direct visibility, as follows:

- A declaration is hidden from direct visibility within the immediate scope of a homograph of the declaration, if the homograph occurs within an inner declarative region;

- A declaration is also hidden from direct visibility where hidden from all visibility.

\{AI95-00195-01\} \{AI95-00408-01\} \{AI05-0183-1\} An attribute_definition_clause or an aspect_specification is visible everywhere within its scope.

Name Resolution Rules

A direct_name shall resolve to denote a directly visible declaration whose defining name is the same as the direct_name. A selector_name shall resolve to denote a visible declaration whose defining name is the same as the selector_name.

Discussion: "The same as" has the obvious meaning here, so for +, the possible interpretations are declarations whose defining name is "+" (an operator_symbol).

These rules on visibility and direct visibility do not apply in a context_clause, a parent_unit_name, or a pragma that appears at the place of a compilation_unit. For those contexts, see the rules in 10.1.6, “Environment-Level Visibility Rules”.

Visibility 8.3
Ramification: Direct visibility is irrelevant for character_literals. In terms of overload resolution character_literals are similar to other literals, like null — see 4.2. For character_literals, there is no need to worry about hiding, since there is no way to declare homographs.

Legality Rules

A nonoverridableAn explicit declaration is illegal if there is a homograph occurring immediately within the same declarative region that is visible at the place of the declaration, and is not hidden from all visibility by the nonoverridable explicit declaration. In addition, a type_extension is illegal if somewhere within its immediate scope it has two visible components with the same name. Similarly, the context_clause for a compilation_unit subunit is illegal if it mentions (in a with_clause) some library unit, and there is a homograph of the library unit that is visible at the place of the compilation_unit corresponding stub, and the homograph and the mentioned library unit are both declared immediately within the same declarative region. These rules also apply to dispatching operations declared in the visible part of an instance of a generic unit. However, they do not apply to other overloadable declarations in an instance; such declarations may have type_conformant profiles in the instance, so long as the corresponding declarations in the generic were not type_conformant].

Discussion: Normally, these rules just mean you can't explicitly declare two homographs immediately within the same declarative region. The wording is designed to handle the following special cases:

- If the second declaration completes the first one, the second declaration is legal.
- If the body of a library unit contains an explicit homograph of a child of that same library unit, this is illegal only if the body mentions the child in its context_clause, or if some subunit mentions the child. Here's an example:

```ada
package P is
end P;
package P.Q is
end P.Q;
package body P is
  Q : Integer; -- OK; we cannot see package P.Q here.
  procedure Sub is separate;
end P;
with P.Q;
procedure Sub is -- Illegal.
begin
  null;
end Sub;
```

If package body P said "with P.Q;", then it would be illegal to declare the homograph Q: Integer. But it does not, so the body of P is OK. However, the subunit would be able to see both P.Q's, and is therefore illegal.

A previous version of Ada 9X allowed the subunit, and said that references to P.Q would tend to be ambiguous. However, that was a bad idea, because it requires overload resolution to resolve references to directly visible nonoverloadable homographs, which is something compilers have never before been required to do.

- If a type_extension contains a component with the same name as a component in an ancestor type, there must be no place where both components are visible. For instance:

```ada
package A is
  type T is tagged private;
  package B is
    type NT is new T with record
      T : Integer; -- Illegal because T.I is visible in the body.
    end record; -- T.I is not visible here.
  end B;
private
  type T is tagged record
    T : Integer; -- Illegal because T.I is visible in the body.
  end record;
end A;
```
package A is
    -- T.I becomes visible here.
end A;

package B is
    -- T.I becomes visible here.
end B;

package A.C is
    type NT2 is new A.T with record
        I: Integer;
    end record;
    -- Illegal because T.I is visible in the private part.
private
    -- T.I is visible here.
end A.C;

with A;
package D is
    type NT3 is new A.T with record
        I: Integer; -- Legal because T.I is never visible in this package.
    end record;
end D;

with D;
package A.E is
    type NT4 is new D.NT3 with null record;
    X : NT4;
    I1 : Integer := X.I; -- D.NT3.I
end A.E;

D.NT3 can have a component I because the component I of the parent type is never visible. The parent component exists, of course, but is never declared for the type D.NT3. In the child package A.E, the component I of A.T is visible, but that does not change the fact that the A.T.I component was never declared for type D.NT3. Thus, A.E.NT4 does not (visibly) inherit the component I from A.T, while it does inherit the component I from D.NT3. Of course, both components exist, and can be accessed by a type conversion as shown above. This behavior stems from the fact that every characteristic of a type (including components) must be declared somewhere in the innermost declarative region containing the type — if the characteristic is never visible in that declarative region, it is never declared. Therefore, such characteristics do not suddenly become available even if they are in fact visible in some other scope. See 7.3.1 for more on the rules.

It is illegal to mention both an explicit child of an instance, and a child of the generic from which the instance was instantiated. This is easier to understand with an example:

```
generic
package G1 is
end G1;

generic
package G1.G2 is
end G1.G2;

with G1;
package I1 is new G1;
```

```
package I1.G2 renames ...
```

```
with G1.G2;
with I1.G2; -- Illegal
```

The context clause for Bad is illegal as I1 has an implicit declaration of I1.G2 based on the generic child G1.G2, as well as the mention of the explicit child I1.G2. As in the previous cases, this is illegal only if the context clause makes both children visible; the explicit child can be mentioned as long as the generic child is not (and vice-versa).

Note that we need to be careful which things we make "hidden from all visibility" versus which things we make simply illegal for names to denote. The distinction is subtle. The rules that disallow names denoting components within a type declaration (see 3.7) do not make the components invisible at those places, so that the above rule makes components with the same name illegal. The same is true for the rule that disallows names denoting formal parameters within a formal_part (see 6.1).

Discussion: The part about instances is from AI83-00012. The reason it says “overloadable declarations” is because we don’t want it to apply to type extensions that appear in an instance; components are not overloadable.

NOTES
5 Visibility for compilation units follows from the definition of the environment in 10.1.4, except that it is necessary to apply a with_clause to obtain visibility to a library_unit_declaration or library_unit_renamingDeclaration.
6 In addition to the visibility rules given above, the meaning of the occurrence of a direct_name or selector_name at a given place in the text can depend on the overloading rules (see 8.6).

7 Not all contexts where an identifier, character_literal, or operator_symbol are allowed require visibility of a corresponding declaration. Contexts where visibility is not required are identified by using one of these three syntactic categories directly in a syntax rule, rather than using direct_name or selector_name.

**Ramification:** An identifier, character_literal or operator_symbol that occurs in one of the following contexts is not required to denote a visible or directly visible declaration:

- **1.** A defining name.
- **2.** The identifiers or operator_symbol that appear after the reserved word end in a proper_body. Similarly for "end loop", etc.
- **3.** An attribute_designator.
- **4.** A pragma identifier.
- **5.** A pragma_argument_identifier.
- **6.** An identifier specific to a pragma used in a pragma argument.
- **7.** An aspect mark.
- **8.** An identifier specific to an aspect used in an aspect_definition.

The visibility rules have nothing to do with the above cases; the meanings of such things are defined elsewhere. Reserved words are not identifiers; the visibility rules don't apply to them either.

Because of the way we have defined "declaration", it is possible for a usage name to denote a subprogram_body, either within that body, or (for a nonlibrary unit) after it (since the body hides the corresponding declaration, if any). Other bodies do not work that way. Completions of type_declaration and deferred constant declarations do work that way. Accept_statements are never denoted, although the parameter_specifications in their profiles can be.

The scope of a subprogram does not start until after its profile. Thus, the following is legal:

```
X : constant Integer := 17;
... package P is
  procedure X(Y : in Integer := X);
end P;
```

The body of the subprogram will probably be illegal, however, since the constant X will be hidden by then.

The rule is different for generic subprograms, since they are not overloadable; the following is illegal:

```
X : constant Integer := 17;
package P is generic
  Z : Integer := X; -- Illegal!
  procedure X(Y : in Integer := X); -- Illegal!
end P;
```

The constant X is hidden from direct visibility by the generic declaration.

**Extensions to Ada 83**

Declarations with the same defining name as that of a subprogram or entry being defined are nevertheless visible within the subprogram specification or entry declaration.

**Wording Changes from Ada 83**

The term “visible by selection” is no longer defined. We use the terms “directly visible” and “visible” (among other things). There are only two regions of text that are of interest, here: the region in which a declaration is visible, and the region in which it is directly visible.

**Visibility is defined only for declarations.**

**Incompatibilities With Ada 95**

```
{AI95-00251-01} Added rules to handle the inheritance and overriding of multiple homographs for a single type declaration, in order to support multiple inheritance from interfaces. The new rules are intended to be compatible with the existing rules so that programs that do not use interfaces do not change their legality. However, there is a very rare case where this is not true.
```
package G is
  type T is null record;
  procedure P (X : T; Y : T1);
  procedure P (X : T; Z : T2);
end G;

package I is new G (Integer, Integer); -- Exports homographs of P.

package D is new I.T; -- Both Ps are inherited.

Obj : D;

P (Obj, Z => 10); -- Legal in Ada 95, illegal in Ada 2005.

The call to P would resolve in Ada 95 by using the parameter name, while the procedures P would be hidden from all visibility in Ada 2005 and thus would not resolve. This case doesn't seem worth making the rules any more complex than they already are.

\{AI95-00377-01\} Amendment Correction: A with_clause is illegal if it would create a homograph of an implicitly declared generic child (see 10.1.1). An Ada 95 compiler could have allowed this, but which unit of the two units involved would be denoted wasn't specified, so any successful use isn't portable. Removing one of the two with_clause involved will fix the problem.

Wording Changes from Ada 95

\{8652/0025\} \{AI95-00044-01\} Corrigendum: Clarified the overriding rules so that "/=" and statement_identifiers are covered.

\{8652/0026\} \{AI95-00150-01\} Corrigendum: Clarified that it is never possible for two components with the same name to be visible; any such program is illegal.

\{AI95-00195-01\} The visibility of an attribute_definition_clause is defined so that it can be used by the stream attribute availability rules (see 13.13.2).

\{AI95-00217-06\} The visibility of a limited view of a library package is defined (see 10.1.1).

Wording Changes from Ada 2005

\{AI05-0177-1\} Added wording so that the parameters of an expression_function_declaration are visible in the expression of the function. (It would be pretty useless without such a rule.)

\{AI05-0183-1\} The visibility of an aspect_specification is defined so that it can be used in various other rules.

8.3.1 Overriding Indicators

\{AI95-00218-03\} An overriding_indicator is used to declare that an operation is intended to override (or not override) an inherited operation.

Syntax

\{AI95-00218-03\} overriding_indicator ::= [not] overriding

Legality Rules

\{AI95-00218-03\} \{AI95-00348-01\} \{AI95-00397-01\} \{AI05-0177-1\} If an abstract_subprogram_declaration, null_procedure_declaration, expression_function_declaration, subprogram_body, subprogram_body_stub, subprogram_renaming_declaration, generic_instantiation of a subprogram, or subprogram_declaration other than a protected subprogram has an overriding_indicator, then:

- the operation shall be a primitive operation for some type;
- if the overriding_indicator is overriding, then the operation shall override a homograph at the place of the declaration or body;

To be honest: \{AI05-0005-1\} This doesn't require that the overriding happen at precisely the place of the declaration or body; it only requires that the region in which the overriding is known to have happened includes this place. That is, the overriding can happen at or before the place of the declaration or body.
• if the overriding indicator is not overriding, then the operation shall not override any homograph (at any place).

In addition to the places where Legality Rules normally apply, these rules also apply in the private part of an instance of a generic unit.

Discussion: The overriding and not overriding rules differ slightly. For overriding, we want the indicator to reflect the overriding state at the place of the declaration; otherwise the indicator would be “lying”. Whether a homograph is implicitly declared after the declaration (see 7.3.1 to see how this can happen) has no impact on this check. However, not overriding is different; “lying” would happen if a homograph declared later actually is overriding. So, we require this check to take into account later overridings. That can be implemented either by looking ahead, or by rechecking when additional operations are declared.

The “no lying” rules are needed to prevent a subprogram declaration and subprogram body from having contradictory overriding indicators.

NOTES

8 {AI95-00397-01} Rules for overriding indicators of task and protected entries and of protected subprograms are found in 9.5.2 and 9.4, respectively.

Examples

{AI95-00433-01} The use of overriding indicators allows the detection of errors at compile-time that otherwise might not be detected at all. For instance, we might declare a security queue derived from the Queue interface of 3.9.4 as:

```ada
type Security_Queue is new Queue with record ...;
overriding
procedure Append(Q : in out Security_Queue; Person : in Person_Name);
overriding
procedure Remove_First(Q : in out Security_Queue; Person : in Person_Name);
overriding
function Cur_Count(Q : in Security_Queue) return Natural;
overriding
function Max_Count(Q : in Security_Queue) return Natural;
not overriding
procedure Arrest(Q : in out Security_Queue; Person : in Person_Name);
```

The first four subprogram declarations guarantee that these subprograms will override the four subprograms inherited from the Queue interface. A misspelling in one of these subprograms will be detected by the implementation. Conversely, the declaration of Arrest guarantees that this is a new operation.

Discussion: In this case, the subprograms are abstract, so misspellings will get detected anyway. But for other subprograms (especially when deriving from concrete types), the error might never be detected, and a body other than the one the programmer intended might be executed without warning. Thus our new motto: “Overriding indicators — don’t derive a type without them!”

Extensions to Ada 95

{AI95-00218-03} Overriding indicators are new. These let the programmer state her overriding intentions to the compiler; if the compiler disagrees, an error will be produced rather than a hard to find bug.

Wording Changes from Ada 2005

{AI95-0177-1} Expression functions can have overriding indicators.

8.4 Use Clauses

[A use_package_clause achieves direct visibility of declarations that appear in the visible part of a package; a use_type_clause achieves direct visibility of the primitive operators of a type.]
Language Design Principles

If and only if the visibility rules allow \textit{P.A}, "\texttt{use P;}" should make \textit{A} directly visible (barring name conflicts). This means, for example, that child library units, and generic formals of a formal package whose \texttt{formal\_package\_actual\_part} is \texttt{(<>)}, should be made visible by a \texttt{use\_clause} for the appropriate package.

The rules for \texttt{use\_clauses} were carefully constructed to avoid so-called \textit{Beaujolais} effects, where the addition or removal of a single \texttt{use\_clause}, or a single declaration in a "\texttt{use}"d package, would change the meaning of a program from one legal interpretation to another.

\textit{Syntax}

\begin{verbatim}
use_clause ::= use\_package\_clause | use\_type\_clause

use\_package\_clause ::= use package\_name {, package\_name};

\{AI05-0150-1\} use\_type\_clause ::= use \texttt{[all]} type\_subtype\_mark {, subtype\_mark};
\end{verbatim}

\textit{Legality Rules}

\{AI95-00217-06\} A \texttt{package\_name} of a \texttt{use\_package\_clause} shall denote a \texttt{nonlimited view of} a package.

\textbf{Ramification:} This includes formal packages.

\textit{Static Semantics}

For each \texttt{use\_clause}, there is a certain region of text called the \textit{scope} of the \texttt{use\_clause}. For a \texttt{use\_clause} within a \texttt{context\_clause} of a \texttt{library\_unit\_declaration} or \texttt{library\_unit\_renaming\_declaration}, the scope is the entire declarative region of the declaration. For a \texttt{use\_clause} within a \texttt{context\_clause} of a body, the scope is the entire body [and any subunits (including multiply nested subunits). The scope does not include \texttt{context\_clauses} themselves.]

For a \texttt{use\_clause} immediately within a declarative region, the scope is the portion of the declarative region starting just after the \texttt{use\_clause} and extending to the end of the declarative region. However, the scope of a \texttt{use\_clause} in the private part of a library unit does not include the visible part of any public descendant of that library unit.

\textbf{Reason:} The exception echoes the similar exception for “immediate scope (of a declaration)” (see 8.2). It makes \texttt{use\_clauses} work like this:

\begin{verbatim}
package P is
  type T is range 1..10;
end P;

with P;
package Parent is
private
  use P;
  X : T;
end Parent;

package Parent.Child is
  Y : T; -- Illegal!
  Z : P.T;
private
  W : T;
end Parent.Child;
\end{verbatim}

The declaration of \texttt{Y} is illegal because the scope of the "\texttt{use P}" does not include that place, so \texttt{T} is not directly visible there. The declarations of \texttt{X}, \texttt{Z}, and \texttt{W} are legal.

\{AI95-00217-06\} \textit{A package is named in a use\_package\_clause if it is denoted by a package\_name of that clause. A type is named in a use\_type\_clause if it is determined by a subtype\_mark of that clause.}  

\{AI95-00217-06\} \{AI05-0150-1\} For each package \texttt{named\_in} denoted by a \texttt{package\_name} of a \texttt{use\_package\_clause} whose scope encloses a place, each declaration that occurs immediately within the declarative region of the package is \texttt{potentially use-visible} at this place if the declaration is visible at this place. For each type \texttt{T} or \texttt{TClass} \texttt{named\_in} determined by a \texttt{subtype\_mark} of a \texttt{use\_type\_clause} whose
scope encloses a place, the declaration of each primitive operator of type \( T \) is potentially use-visible at this place if its declaration is visible at this place. If a use_type_clause whose scope encloses a place includes the reserved word all, then the following entities are also potentially use-visible at this place if the declaration of the entity is visible at this place:

- \{AI05-0150-1\} Each primitive subprogram of \( T \) including each enumeration literal (if any);
- \{AI05-0150-1\} Each subprogram that is declared immediately within the declarative region in which an ancestor type of \( T \) is declared and that operates on a class-wide type that covers \( T \).

**Ramification:** \{AI05-0150-1\} Primitive subprograms whose defining name is an identifier are not made potentially visible by a use_type_clause unless reserved word all is included. A use_type_clause without all is only for operators.

The semantics described here should be similar to the semantics for expanded names given in 4.1.3, “Selected Components” so as to achieve the effect requested by the “principle of equivalence of use_clauses and selected_components.” Thus, child library units and generic formal parameters of a formal package are potentially use-visible when their enclosing package is use’d.

The “visible at that place” part implies that applying a use_clause to a parent unit does not make all of its children use-visible — only those that have been made visible by a with_clause. It also implies that we don't have to worry about hiding in the definition of “directly visible” — a declaration cannot be use-visible unless it is visible.

Note that "use type TClass;" is equivalent to "use type T;", which helps avoid breaking the generic contract model.

**Ramification:** Overloadable declarations don't cancel each other out, even if they are homographs, though if they are not distinguishable by formal parameter names or the presence or absence of default_expressions, any use will be ambiguous. We only mention identifiers here, because declarations named by operator_symbols are always overloadable, and hence never cancel each other. Direct visibility is irrelevant for character_literals.

**Dynamic Semantics**

The elaboration of a use_clause has no effect.

**Example of a use clause in a context clause:**

```ada
with Ada.Calendar; use Ada;
```

**Example of a use type clause:**

```ada
use type Rational_Numbers.Rational; -- see 7.1
Two_Thirds: Rational_Numbers.Rational := 2/3;
```

**Ramification:** In “use X; Y;” Y cannot refer to something made visible by the “use” of X. Thus, it's not (quite) equivalent to “use X; use Y;”.

If a given declaration is already immediately visible, then a use_clause that makes it potentially use-visible has no effect. Therefore, a use_type_clause for a type whose declaration appears in a place other than the visible part of a package has no effect; it cannot make a declaration use-visible unless that declaration is already immediately visible.

"Use type S1;" and "use type S2;" are equivalent if S1 and S2 are both subtypes of the same type. In particular, "use type S;" and "use type S'Base;" are equivalent.

**Reason:** We considered adding a rule that prevented several declarations of views of the same entity that all have the same semantics from cancelling each other out. For example, if a (possibly implicit) subprogram_declaration for "+" is potentially use-visible, and a fully conformant renaming of it is also potentially use-visible, then they (annoyingly)
cancel each other out; neither one is use-visible. The considered rule would have made just one of them use-visible. We gave up on this idea due to the complexity of the rule. It would have had to account for both overloadable and nonoverloadable renaming declarations, the case where the rule should apply only to some subset of the declarations with the same defining name, and the case of subtype declarations (since they are claimed to be sufficient for renaming of subtypes).

Extensions to Ada 83

The use_type_clause is new to Ada 95.

Wording Changes from Ada 83

The phrase “omitting from this set any packages that enclose this place” is no longer necessary to avoid making something visible outside its scope, because we explicitly state that the declaration has to be visible in order to be potentially use-visible.

Wording Changes from Ada 95

{AI95-00217-06} Limited views of packages are not allowed in use clauses. Defined named in a use clause for use in other limited view rules (see 10.1.2).

Extensions to Ada 2005

{AI05-0150-1} The use all type version of the use_type_clause is new to Ada 2012. It works similarly to prefixed views.

Wording Changes from Ada 2005

{AI05-0131-1} Correction: Added wording to allow other declarations to be potentially use-visible, to support corrections to formal subprograms.

8.5 Renaming Declarations

[A renaming_declaration declares another name for an entity, such as an object, exception, package, subprogram, entry, or generic unit. Alternatively, a subprogram_renaming_declaration can be the completion of a previous subprogram_declaration.]

Glossary entry: A renaming_declaration is a declaration that does not define a new entity, but instead defines a view of an existing entity.

Syntax

renaming_declaration ::= object_renaming_declaration | exception_renaming_declaration | package_renaming_declaration | subprogram_renaming_declaration | generic_renaming_declaration

Dynamic Semantics

The elaboration of a renaming_declaration evaluates the name that follows the reserved word renaming and thereby determines the view and entity denoted by this name (the renamed view and renamed entity).

[An object that denotes the renaming_declaration denotes (a new view of) the renamed entity.]

NOTES

9 Renaming may be used to resolve name conflicts and to act as a shorthand. Renaming with a different identifier or operator_symbol does not hide the old name; the new name and the old name need not be visible at the same places.

10 A task or protected object that is declared by an explicit object_declaration can be renamed as an object. However, a single task or protected object cannot be renamed since the corresponding type is anonymous (meaning it has no nameable subtypes). For similar reasons, an object of an anonymous array or access type cannot be renamed.
11 A subtype defined without any additional constraint can be used to achieve the effect of renaming another subtype (including a task or protected subtype) as in

```ada
subtype Mode is Ada.Text_IO.File_Mode;
```

### Wording Changes from Ada 83

7.a The second sentence of RM83-8.5(3), “At any point where a renaming declaration is visible, the identifier, or operator symbol of this declaration denotes the renamed entity.” is incorrect. It doesn't say directly visible. Also, such an identifier might resolve to something else.

7.b The verbiage about renamings being legal “only if exactly one...”, which appears in RM83-8.5(4) (for objects) and RM83-8.5(7) (for subprograms) is removed, because it follows from the normal rules about overload resolution. For language lawyers, these facts are obvious; for programmers, they are irrelevant, since failing these tests is highly unlikely.

### 8.5.1 Object Renaming Declarations

[An object_renaming_declaration is used to rename an object.]

#### Syntax

```ada
{AI95-00230-01} {AI95-00423-01} {AI05-0183-1} object_renaming_declaration ::=  
  defining_identifier : [null_exclusion] subtype_mark renames object_name  
  [aspect_specification];  
  | defining_identifier : access_definition renames object_name  
  [aspect_specification];
```

#### Name Resolution Rules

3/2 `{AI95-00230-01} {AI95-00254-01} {AI95-00409-01}` The type of the `object_name` shall resolve to the type determined by the `subtype_mark`, or in the case where the type is defined by an `access_definition`, to an anonymous access type. If the anonymous access type is an access-to-object type, the type of the `object_name` shall have the same designated type as that of the `access_definition`. If the anonymous access type is an access-to-subprogram type, the type of the `object_name` shall have a designated profile that is type conformant with that of the `access_definition`.

3.b Reason: A previous version of Ada 9X used the usual “expected type” wording:

“The expected type for the `object_name` is that determined by the `subtype_mark`.”

We changed it so that this would be illegal:

```ada
X: T;  
Y: T'Class renames X; -- Illegal!
```

3.c When the above was legal, it was unclear whether Y was of type T or T'Class. Note that we still allow this:

```ada
Z: T'Class := ...;  
W: T renames F(Z);
```

3.f where F is a function with a controlling parameter and result. This is admittedly a bit odd.

Note that the matching rule for generic formal parameters of mode `in out` was changed to keep it consistent with the rule for renaming. That makes the rule different for `in` vs. `in out`.

#### Legality Rules

4 The renamed entity shall be an object.

4.1/2 `{AI95-00231-01} {AI95-00409-01}` In the case where the type is defined by an `access_definition`, the type of the renamed object and the type defined by the `access_definition`:

- `{AI95-00231-01} {AI95-00409-01}` shall both be access-to-object types with statically matching designated subtypes and with both or neither being access-to-constant types; or

- `{AI95-00409-01}` shall both be access-to-subprogram types with subtype conformant designated profiles.
For an object_renaming_declaration with a null_exclusion or an access_definition that has a null_exclusion:

- if the object_name denotes a generic formal object of a generic unit G, and the object_renaming_declaration occurs within the body of G or within the body of a generic unit declared within the declarative region of G, then the declaration of the formal object of G shall have a null_exclusion;

- otherwise, the subtype of the object_name shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Reason: This rule prevents “lying”. Null must never be the value of an object with an explicit null_exclusion. The first bullet is an assume-the-worst rule which prevents trouble in one obscure case:

```ada
type Acc_I is access Integer;
subtype Acc_NN_I is not null Acc_I;
Obj : Acc_I := null;
generic
  B : in out Acc_NN_I;
package Gen is
  ...
end Gen;
package body Gen is
  B : not null Acc_I renames B;
end Gen;
package Inst is new Gen (B => Obj);
```

Without the first bullet rule, D would be legal, and contain the value null, because the rule about lying is satisfied for generic matching (Obj matches B; B does not explicitly state not null). Legality Rules are not rechecked in the body of any instance, and the template passes the lying rule as well. The rule is so complex because it has to apply to formals used in bodies of child generics as well as in the bodies of generics.

The renamed entity shall not be a subcomponent that depends on discriminants of an object whose nominal subtype is unconstrained, unless the object is known to be constrained this subtype is indefinite, or the variable is constrained by its initial value aliased. A slice of an array shall not be renamed if this restriction disallows renaming of the array. In addition to the places where Legality Rules normally apply, these rules apply also in the private part of an instance of a generic unit. These rules also apply for a renaming that appears in the body of a generic unit, with the additional requirement that even if the nominal subtype of the variable is indefinite, its type shall not be a descendant of an untagged generic formal derived type.

Reason: This prevents renaming of subcomponents that might disappear, which might leave dangling references. Similar restrictions exist for the Access attribute.

The “recheck on instantiation” requirement and “assume the worst in the body” restrictions on generics are necessary to avoid renaming of components which could disappear even when the nominal subtype would prevent the problem:

```ada
type T1 (D1 : Boolean) is
  record
    case D1 is
      when False =>
        C1 : Integer;
      when True =>
        null;
    end case;
  end record;
generic
  type F is new T1;
X : in out F;
package G is
  C1 Ren : Integer renames X.C1;
end G;
```

8.5.1 Object Renaming Declarations

5.a.4/1

```ada
type T2 (D2 : Boolean := False) is new T1 (D1 => D2);
Y : T2;

package I is new G (T2, Y);
Y := (D1 => True); -- Oops! What happened to I.C1_Ren?
```

5.a.5/3

```ada
{AI05-0008-1} In addition, the “known to be constrained” rules include assume-the-worst rules for generic bodies partially to prevent such problems.
```

5.b

**Implementation Note:** Note that if an implementation chooses to deallocate-then-reallocate on assignment-statements assigning to unconstrained definite objects, then it cannot represent renamings and access values as simple addresses, because the above rule does not apply to all components of such an object.

5.c

**Ramification:** If it is a generic formal object, then the assume-the-best or assume-the-worst rules are applied as appropriate.

### Static Semantics

6/2

```ada
{AI95-00230-01} {AI95-00409-01} An object_renaming_declaration declares a new view [of the renamed object] whose properties are identical to those of the renamed view. [Thus, the properties of the renamed object are not affected by the renaming_declaration. In particular, its value and whether or not it is a constant are unaffected; similarly, the null exclusion or constraints that apply to an object are not affected by renaming (any constraint implied by the subtype_mark or access_definition of the object_renaming_declaration is ignored).]
```

6.a

**Discussion:** Because the constraints are ignored, it is a good idea to use the nominal subtype of the renamed object when writing an object_renaming_declaration.

6.b/2

```ada
{AI95-00409-01} If no null_exclusion is given in the renaming, the object may or may not exclude null. This is similar to the way that constraints need not match, and constant is not specified. The renaming defines a view of the renamed entity, inheriting the original properties.
```

### Examples

7

**Example of renaming an object:**

8

```ada
declare
L : Person renames Leftmost_Person; -- see 3.10.1
begin
L.Age := L.Age + 1;
end;
```

8.a

The phrase “subtype ... as defined in a corresponding object declaration, component declaration, or component subtype indication,” from RM83-8.5(5), is incorrect in Ada 95; therefore we removed it. It is incorrect in the case of an object with an indefinite unconstrained nominal subtype.

8.b/2

```ada
{AI95-00363-01} Aliased variables are not necessarily constrained in Ada 2005 (see 3.6). Therefore, a subcomponent of an aliased variable may disappear or change shape, and renaming such a subcomponent thus is illegal, while the same operation would have been legal in Ada 95. Note that most allocated objects are still constrained by their initial value (see 4.8), and thus have no change in the legality of renaming for them. For example, using the type T2 of the previous example:
```

8.c/2

```ada
AT2 : aliased T2;
C1 Ren : Integer renames AT2.C1; -- Illegal in Ada 2005, legal in Ada 95
AT2 := (D1 => True); -- Raised Constraint_Error in Ada 95,
-- but does not in Ada 2005, so C1_Ren becomes
-- invalid when this is assigned.
```

8.d/2

```ada
{AI95-00230-01} {AI95-00231-01} {AI95-00254-01} {AI95-00409-01} A renaming can have an anonymous access type. In that case, the accessibility of the renaming is that of the original object (accessibility is not lost as it is for assignment to a component or stand-alone object).
```
8.5.1 Renaming Declarations

A renaming can have a null exclusion; if so, the renamed object must also exclude null, so that the null exclusion does not lie. On the other hand, if the renaming does not have a null exclusion, it excludes null if the renamed object does.

Wording Changes from Ada 95

Corrigendum: Fixed to forbid renamings of depends-on-discriminant components if the type might be definite.

Incompatibilities With Ada 2005

Correction: Simplified the description of when a discriminant-dependent component is allowed to be renamed — it's now simply when the object is known to be constrained. This fixes a confusion as to whether a subcomponent of an object that is not certain to be constrained can be renamed. The fix introduces an incompatibility, as the rule did not apply in Ada 95 if the prefix was a constant, but it now applies no matter what kind of object is involved. The incompatibility is not too bad, since most kinds of constants are known to be constrained.

Extensions to Ada 2005

An optional aspect specification can be used in an object renaming declaration. This is described in 13.1.1.

8.5.2 Exception Renaming Declarations

An exception renaming declaration is used to rename an exception.

Syntax

exception renaming declaration ::=
  defining identifier : exception renames exception name
  [aspect specification];

Legality Rules

The renamed entity shall be an exception.

Static Semantics

An exception renaming declaration declares a new view [of the renamed exception].

Examples

Example of renaming an exception:

EOF : exception renames Ada.IO_Exceptions.End_Error; -- see A.13

Extensions to Ada 2005

An optional aspect specification can be used in an exception renaming declaration. This is described in 13.1.1.

8.5.3 Package Renaming Declarations

A package renaming declaration is used to rename a package.

Syntax

package renaming declaration ::= 
  package defining program unit name renames package name
  [aspect specification];

Legality Rules

The renamed entity shall be a package.
If the package name of a package renaming declaration denotes a limited view of a package \( P \), then a name that denotes the package renaming declaration shall occur only within the immediate scope of the renaming or the scope of a with clause that mentions the package \( P \) or, if \( P \) is a nested package, the innermost library package enclosing \( P \).

Discussion: The use of a renaming that designates a limited view is restricted to locations where we know whether the view is limited or nonlimited (based on a with clause). We don't want to make an implicit limited view, as those are not transitive like a regular view. Implementations should be able to see all limited views needed based on the context clause.

Static Semantics

A package renaming declaration declares a new view [of the renamed package].

At places where the declaration of the limited view of the renamed package is visible, a name that denotes the package renaming declaration denotes a limited view of the package (see 10.1.1).

Proof: This rule is found in 8.3, “Visibility”.

Examples

Example of renaming a package:

```ada
package TM renames Table_Manager;
```

Wording Changes from Ada 95

Uses of renamed limited views of packages can only be used within the scope of a with clause for the renamed package.

Extensions to Ada 2005

An optional aspect specification can be used in a package renaming declaration. This is described in 13.1.1.

8.5.4 Subprogram Renaming Declarations

A subprogram renaming declaration can serve as the completion of a subprogram declaration; such a renaming declaration is called a renaming-as-body. A subprogram renaming declaration that is not a completion is called a renaming-as-declaration[, and is used to rename a subprogram (possibly an enumeration literal) or an entry].

Ramification: A renaming-as-body is a declaration, as defined in ClauseSection 3.

Syntax

```
subprogram_renaming_declaration ::= ...
subprogram_specification renames callable_entity_name 
[aspect_specification];
```

Name Resolution Rules

The expected profile for the callable_entity_name is the profile given in the subprogram_specification.

Legality Rules

The profile of a renaming-as-declaration shall be mode_conformant, with that of the renamed callable entity.

For a parameter or result subtype of the subprogram_specification that has an explicit null_exclusion:
• if the callable_entity_name denotes a generic formal subprogram of a generic unit \( G \), and the subprogram_renaming_declaration occurs within the body of a generic unit \( G \) or within the body of a generic unit declared within the declarative region of the generic unit \( G \), then the corresponding parameter or result subtype of the formal subprogram of \( G \) shall have a null exclusion;

• otherwise, the subtype of the corresponding parameter or result type of the renamed callable entity shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

**Reason:** This rule prevents “lying”. Null must never be the value of a parameter or result with an explicit null_exclusion. The first bullet is an assume-the-worst rule which prevents trouble in generic bodies (including bodies of child units) when the formal subtype excludes null implicitly.

\{8652/0027\} \{8652/0028\} \{AI95-00145-01\} \{AI95-00145-01\} \{AI95-00239-1\} The profile of a renaming-as-body shall be subtype_conformant with that of the renamed callable entity, and shall conform fully to that of the declaration it completes. If the renaming-as-body completes that declaration before the subprogram it declares is frozen, the profile shall be mode_conformant with that of the renamed callable entity and the subprogram it declares takes its convention from the renamed subprogram; otherwise, the profile shall be subtype_conformant with that of the renamed callable entity and the convention of the renamed subprogram shall not be Intrinsic. A renaming-as-body is illegal if the declaration occurs before the subprogram whose declaration it completes is frozen, and the renaming renames the subprogram itself, through one or more subprogram renaming declarations, none of whose subprograms has been frozen.

**Reason:** The otherwise part of the second sentence first part of the first sentence is to allow an implementation of a renaming-as-body as a single jump instruction to the target subprogram. Among other things, this prevents a subprogram from being completed with a renaming of an entry. (In most cases, the target of the jump can be filled in at link time. In some cases, such as a renaming of a name like "A(I).all", an indirect jump is needed. Note that the name is evaluated at renaming time, not at call time.)

\{8652/0028\} \{AI95-00145-01\} The first part of the second sentence is intended to allow renaming-as-body of predefined operators before the subprogram declaration is frozen. For some types (such as integer types), the parameter type for operators is the base type, and it would be very strange for

```ada
function Equal (A, B : in T) return Boolean;
```

to be illegal. (Note that predefined operators cannot be renamed this way after the subprogram_declaration is frozen, as they have convention Intrinsic.)

The second part of the first sentence is the normal rule for completions of subprogram_declarations.

**Ramification:** An entry_declaration, unlike a subprogram_declaration, cannot be completed with a renaming_declaration. Nor can a generic_subprogram_declaration.

The syntax rules prevent a protected subprogram declaration from being completed by a renaming. This is fortunate, because it allows us to avoid worrying about whether the implicit protected object parameter of a protected operation is involved in the conformance rules.

**Reason:** \{8652/0027\} \{AI95-00135-01\} Circular renames before freezing is illegal, as the compiler would not be able to determine the convention of the subprogram. Other circular renames are handled below; see Bounded (Run-Time) Errors.

\{AI95-00228-01\} The callable_entity_name of a renaming shall not denote a subprogram that requires overriding (see 3.9.3).

**Reason:** \{AI95-00228-01\} Such a rename cannot be of the inherited subprogram (which requires overriding because it cannot be called), and thus cannot squirrel away a subprogram (see below). That would be confusing, so we make it illegal. The renaming is allowed after the overriding, as then the name will denote the overriding subprogram, not the inherited one.

\{AI95-00228-01\} The callable_entity_name of a renaming-as-body shall not denote an abstract subprogram.

**Reason:** \{AI95-00228-01\} Such a subprogram has no body, so it hardly can replace one in the program.
A name that denotes a formal parameter of the subprogram_specification is not allowed within the callable_entity_name.

Reason: This is to prevent things like this:

```ada
function F(X : Integer) return Integer renames Table(X).all;
```

A similar rule in 6.1 forbids things like this:

```ada
function F(X : Integer; Y : Integer := X) return Integer;
```

Static Semantics

A renaming-as-declaration declares a new view of the renamed entity. The profile of this new view takes its subtypes, parameter modes, and calling convention from the original profile of the callable entity, while taking the formal parameter names and default_expressions from the profile given in the subprogram_renaming_declaration. The new view is a function or procedure, never an entry.

To be honest: When renaming an entry as a procedure, the compile-time rules apply as if the new view is a procedure, but the run-time semantics of a call are that of an entry call.

Ramification: For example, it is illegal for the entry_call_statement of a timed_entry_call to call the new view. But what looks like a procedure call will do things like barrier waiting.

All properties of the renamed entity are inherited by the new view unless otherwise stated by this International Standard. In particular, if the renamed entity is abstract or requires overriding (see 3.9.3), the new view also is abstract or requires overriding. (The renaming will often be illegal in these cases, as a renaming cannot be overridden.) Similarly, if the renamed entity is not a program unit, then neither is the renaming. (Implicitly declared subprograms are not program units, see 10.1).

Dynamic Semantics

For a call to a subprogram whose body is given as a renaming-as-body, the execution of the renaming-as-body is equivalent to the execution of a subprogram_body that simply calls the renamed subprogram with its formal parameters as the actual parameters and, if it is a function, returns the value of the call.

Ramification: This implies that the subprogram completed by the renaming-as-body has its own elaboration check.

For a call on a renaming of a dispatching subprogram that is overridden, if the overriding occurred before the renaming, then the body executed is that of the overriding declaration, even if the overriding declaration is not visible at the place of the renaming; otherwise, the inherited or predefined subprogram is called. A corresponding rule applies to a call on a renaming of a predefined equality operator for an untagged record type.

Discussion: Note that whether or not the renaming is itself primitive has nothing to do with the renamed subprogram. Note that the above rule is only for tagged types and equality of untagged record types.

Consider the following example:

```ada
package P is
  type T is tagged null record;
  function Predefined_Equal(X, Y : T) return Boolean renames "=";
private
  function "="(X, Y : T) return Boolean; -- Override predefined "=".
end P;

with P; use P;
package Q is
  function User_DEFINED_Equal(X, Y : T) return Boolean renames P."=";
end Q;
```

A call on Predefined_Equal will execute the predefined equality operator of T, whereas a call on User_DEFINED_Equal will execute the body of the overriding declaration in the private part of P.

Thus a renaming allows one to squirrel away a copy of an inherited or predefined subprogram before later overriding it.
If a subprogram directly or indirectly renames itself, then it is a bounded error to call that subprogram. Possible consequences are that Program_Error or Storage_Error is raised, or that the call results in infinite recursion.

**Reason:** This has to be a bounded error, as it is possible for a renaming-as-body appearing in a package body to cause this problem. Thus it is not possible in general to detect this problem at compile time.

**NOTES**

12 A procedure can only be renamed as a procedure. A function whose defining_designator is either an identifier or an operator_symbol can be renamed with either an identifier or an operator_symbol; for renaming as an operator, the subprogram specification given in the renaming_declaration is subject to the rules given in 6.6 for operator declarations. Enumeration literals can be renamed as functions; similarly, attribute_references that denote functions (such as references to Succ and Pred) can be renamed as functions. An entry can only be renamed as a procedure; the new name is only allowed to appear in contexts that allow a procedure name. An entry of a family can be renamed, but an entry family cannot be renamed as a whole.

13 The operators of the root numeric types cannot be renamed because the types in the profile are anonymous, so the corresponding specifications cannot be written; the same holds for certain attributes, such as Pos.

14 Calls with the new name of a renamed entry are procedure_call_statements and are not allowed at places where the syntax requires an entry_call_statement in conditional_ and timed_entry_calls, nor in an asynchronous_select; similarly, the Count attribute is not available for the new name.

15 The primitiveness of a renaming-as-declaration is determined by its profile, and by where it occurs, as for any declaration of (a view of) a subprogram; primitiveness is not determined by the renamed view. In order to perform a dispatching call, the subprogram name has to denote a primitive subprogram, not a nonprimitive renaming of a primitive subprogram.

**Examples of subprogram renaming declarations:**

- **procedure** My_Write(C : in Character) renames Pool(K).Write; -- see 4.1.3
- **function** Real_Plus(Left, Right : Real   ) return Real renames "+";
- **function** Int_Plus (Left, Right : Integer) return Integer renames "+";
- **function** Rouge return Color renames Red; -- see 3.5.1
- **function** Rot return Color renames Red;
- **function** Rosso return Color renames Rouge;
- **function** Next(X : Color) return Color renames Color'Succ; -- see 3.5.1

**Example of a subprogram renaming declaration with new parameter names:**

**function** "*" (X,Y : Vector) return Real renames Dot_Product; -- see 6.1

**Example of a subprogram renaming declaration with a new default expression:**

**function** Minimum(L : Link := Head) return Cell renames Min_Cell; -- see 6.1

**Extensions to Ada 95**

- **Corrigendum:** Allowed a renaming-as-body to be just mode conformant with the specification if the subprogram is not yet frozen.
- **Corrigendum:** Overriding_indicator (see 8.3.1) is optionally added to subprogram renamings.

**Wording Changes from Ada 95**

- **Corrigendum:** Described the semantics of renaming-as-body, so that the location of elaboration checks is clear.
8.5.4 Subprogram Renaming Declarations

8.5.5 Generic Renaming Declarations

[A generic_renaming_declaration is used to rename a generic unit.]

Syntax

```
{AI05-0183-1} generic_renaming_declaration ::= 
    generic package defining_program_unit_name renames generic_package_name |
        [aspect_specification]; |
    generic procedure defining_program_unit_name renames generic_procedure_name |
        [aspect_specification]; |
    generic function defining_program_unit_name renames generic_function_name |
        [aspect_specification];
```

Legality Rules

3 The renamed entity shall be a generic unit of the corresponding kind.

Static Semantics

4 A generic_renaming_declaration declares a new view [of the renamed generic unit].

NOTES

16 Although the properties of the new view are the same as those of the renamed view, the place where the generic_renaming_declaration occurs may affect the legality of subsequent renamings and instantiations that denote the generic_renaming_declaration, in particular if the renamed generic unit is a library unit (see 10.1.1).

Examples

5 Example of renaming a generic unit:

```
generic package Enum_IO renames Ada.Text_IO Enumeration_IO; -- see A.10.10
```

Extensions to Ada 83

7.a Renaming of generic units is new to Ada 95. It is particularly important for renaming child library units that are generic units. For example, it might be used to rename Numerics.Generic_Elementary_Functions as simply Generic_Elementary_Functions, to match the name for the corresponding Ada-83-based package.

Wording Changes from Ada 83

7.b The information in RM83-8.6, “The Package Standard,” has been updated for the child unit feature, and moved to Annex A, except for the definition of “predefined type,” which has been moved to 3.2.1.
8.6 The Context of Overload Resolution

{AI05-0299-1} [ Because declarations can be overloaded, it is possible for an occurrence of a usage name to have more than one possible interpretation; in most cases, ambiguity is disallowed. This subclause describes how the possible interpretations resolve to the actual interpretation.

Certain rules of the language (the Name Resolution Rules) are considered “overloading rules”. If a possible interpretation violates an overloading rule, it is assumed not to be the intended interpretation; some other possible interpretation is assumed to be the actual interpretation. On the other hand, violations of nonoverloading rules do not affect which interpretation is chosen; instead, they cause the construct to be illegal. To be legal, there usually has to be exactly one acceptable interpretation of a construct that is a “complete context”, not counting any nested complete contexts.

The syntax rules of the language and the visibility rules given in 8.3 determine the possible interpretations. Most type checking rules (rules that require a particular type, or a particular class of types, for example) are overloading rules. Various rules for the matching of formal and actual parameters are overloading rules.]

Language Design Principles

The type resolution rules are intended to minimize the need for implicit declarations and preference rules associated with implicit conversion and dispatching operations.

Name Resolution Rules

[Overload resolution is applied separately to each complete context, not counting inner complete contexts.] Each of the following constructs is a complete context:

- A context_item.
- A declarative_item or declaration.
  Ramification: A loop_parameter_specification is a declaration, and hence a complete context.
- A statement.
- A pragma_argument_association.
  Reason: We would make it the whole pragma, except that certain pragma arguments are allowed to be ambiguous, and ambiguity applies to a complete context.
- The expression of a case_statement.
  Ramification: This means that the expression is resolved without looking at the choices.

An (overall) interpretation of a complete context embodies its meaning, and includes the following information about the constituents of the complete context, not including constituents of inner complete contexts:

- for each constituent of the complete context, to which syntactic categories it belongs, and by which syntax rules; and
  Ramification: Syntax categories is plural here, because there are lots of trivial productions — an expression might also be all of the following, in this order: identifier, name, primary, factor, term, simple_expression, and relation. Basically, we’re trying to capture all the information in the parse tree here, without using compiler-writer’s jargon like “parse tree”.
- for each usage name, which declaration it denotes (and, therefore, which view and which entity it denotes); and
12.2  Ramification: \(\{A195-00382-01\}\) In most cases, a usage name denotes the view declared by the denoted declaration. However, in certain cases, a usage name that denotes a declaration and appears inside the declarative region of that same declaration, denotes the current instance of the declaration. For example, within a \texttt{task\_body} other than \texttt{in an access\_definition}, a usage name that denotes the \texttt{task\_type\_declaration} denotes the object containing the currently executing task, and not the task type declared by the declaration.

- for a complete context that is a \texttt{declarative\_item}, whether or not it is a completion of a declaration, and (if so) which declaration it completes.

13  Ramification: Unfortunately, we are not confident that the above list is complete. We'll have to live with that.

13.a  To be honest: For “possible” interpretations, the above information is tentative.

13.b  Discussion: A possible interpretation (an \texttt{input} to overload resolution) contains information about what a usage name might denote, but what it actually \texttt{does} denote requires overload resolution to determine. Hence the term “tentative” is needed for possible interpretations; otherwise, the definition would be circular.

14  A possible interpretation is one that obeys the syntax rules and the visibility rules. An acceptable interpretation is a possible interpretation that obeys the overloading rules[1], that is, those rules that specify an expected type or expected profile, or specify how a construct shall \texttt{resolve} or be \texttt{interpreted}.

14.a  To be honest: One rule that falls into this category, but does not use the above-mentioned magic words, is the rule about numbers of parameter associations in a call (see 6.4).

14.b  Ramification: The Name Resolution Rules are the ones that appear under the Name Resolution Rules heading. Some Syntax Rules are written in English, instead of BNF. No rule is a Syntax Rule or Name Resolution Rule unless it appears under the appropriate heading.

15  The interpretation of a constituent of a complete context is determined from the overall interpretation of the complete context as a whole. [Thus, for example, “interpreted as a \texttt{function\_call},” means that the construct’s interpretation says that it belongs to the syntactic category \texttt{function\_call}.]

16  [Each occurrence of] a usage name \texttt{denotes} the declaration determined by its interpretation. It also denotes the view declared by its denoted declaration, except in the following cases:

16.a  Ramification: As explained below, a pragma argument is allowed to be ambiguous, so it can denote several declarations, and all of the views declared by those declarations.

17.3  \(\{A195-00382-01\} \{A105-0287-1\}\) If a usage name appears within the declarative region of a \texttt{type\_declaration} and denotes that same \texttt{type\_declaration}, then it denotes the current instance of the type (rather than the type itself). The current instance of a type is the object or value of the type that is associated with the execution that evaluates the usage name. Similarly, if a usage name appears within the declarative region of a \texttt{subtype\_declaration} and denotes that same \texttt{subtype\_declaration}, then it denotes the current instance of the subtype. These rules do not apply if the usage name appears within the \texttt{subtype\_mark} of an \texttt{access\_definition} for an \texttt{access\_to\_object\_type}, or within the \texttt{subtype\_of} of a \texttt{parameter} or result of an \texttt{access\_to\_subprogram\_type}.

17.a2  Reason: \(\{A195-00382-01\}\) This is needed, for example, for references to the Access attribute from within the \texttt{type\_declaration}. Also, within a \texttt{task\_body} or \texttt{protected\_body}, we need to be able to denote the current task or protected object. (For a \texttt{single\_task\_declaration} or \texttt{single\_protected\_declaration}, the rule about current instances is not needed.) We exclude anonymous access types so that they can be used to create self-referencing types in the natural manner (otherwise such types would be illegal).

17.b2  Discussion: \(\{A195-00382-01\}\) The phrase “within the \texttt{subtype\_mark}” in the “this rule does not apply” part is intended to cover a case like \texttt{access T\_Class} appearing within the declarative region of \texttt{T}: here \texttt{T} denotes the type, not the current instance.

18  If a usage name appears within the declarative region of a \texttt{generic\_declaration} (but not within its \texttt{generic\_formal\_part}) and it denotes that same \texttt{generic\_declaration}, then it denotes the current instance of the generic unit (rather than the generic unit itself). See also 12.3.

18.a  To be honest: The current instance of a generic unit is the instance created by whichever \texttt{generic\_instantiation} is of interest at any given time.

18.b  Ramification: Within a \texttt{generic\_formal\_part}, a name that denotes the \texttt{generic\_declaration} denotes the generic unit, which implies that it is not overloadable.
A usage name that denotes a view also denotes the entity of that view.

**Ramification:** Usually, a usage name denotes only one declaration, and therefore one view and one entity.

{AI95-00231-01} The **expected type** for a given expression, name, or other construct determines, according to the **type resolution rules** given below, the types considered for the construct during overload resolution. [The type resolution rules provide support for class-wide programming, universal numeric literals, dispatching operations, and anonymous access types:]

**Ramification:** Expected types are defined throughout the RM95. The most important definition is that, for a subprogram, the expected type for the actual parameter is the type of the formal parameter.

The type resolution rules are trivial unless either the actual or expected type is universal, class-wide, or of an anonymous access type.

- If a construct is expected to be of any type in a class of types, or of the universal or class-wide type for a class, then the type of the construct shall resolve to a type in that class or to a universal type that covers the class.

**Ramification:** This matching rule handles (among other things) cases like the Val attribute, which denotes a function that takes a parameter of type `universal_integer`.

The last part of the rule, “or to a universal type that **covers** the class” implies that if the expected type for an expression is `universal_fixed`, then an expression whose type is `universal_real` (such as a real literal) is OK.

- If the expected type for a construct is a specific type \( T \), then the type of the construct shall resolve either to \( T \), or:

**Ramification:** This rule is **not** intended to create a preference for the specific type — such a preference would cause Beaujolais effects.

  - to \( T \text{Class} \);
  
  - to a universal type that covers \( T \); or

**Ramification:** This will only be legal as part of a call on a dispatching operation; see 3.9.2, “Dispatching Operations of Tagged Types”. Note that that rule is not a Name Resolution Rule.

  - to a universal type that covers \( T \); or

**Ramification:** This paragraph was deleted. **Ramification:** \{AI95-00409-01\} Because it says “access-to-variable” instead of “access-to-object,” two subprograms that differ only in that one has a parameter of an access-to-constant type, and the other has an access parameter, are distinguishable during overload resolution.

The case where the actual is access-to-\( D \)Class will only be legal as part of a call on a dispatching operation; see 3.9.2, “Dispatching Operations of Tagged Types”. Note that that rule is not a Name Resolution Rule.

- \{AI05-0149-1\} when \( T \) is a named general access-to-object type (see 3.10) with designated type \( D \), to an access-to-object variable type whose designated type is \( D \text{Class} \) or is covered by \( D \); or

**Ramification:** \{AI95-00230-01\} \{AI95-00231-01\} \{AI95-00254-01\} \{AI95-00409-01\} when \( T \) is a **specific** anonymous access-to-object type (see 3.10) with designated type \( D \), to an access-to-object variable type whose designated type is \( D \text{Class} \) or is covered by \( D \);

This paragraph was deleted. **Ramification:** \{AI95-00409-01\} Because it says “access-to-variable” instead of “access-to-object,” two subprograms that differ only in that one has a parameter of an access-to-constant type, and the other has an access parameter, are distinguishable during overload resolution.

- \{AI95-00230-01\} \{AI95-00231-01\} \{AI95-00409-01\} \{AI05-0239-1\} when \( T \) is a **named** access-to-subprogram type (see 3.10), to an access-to-subprogram type whose designated profile is type conformant with that of \( T \).

In certain contexts, [such as in a subprogram_renaming_declaration,] the Name Resolution Rules define an **expected profile** for a given **name**; in such cases, the **name** shall resolve to the name of a callable entity whose profile is type conformant with the expected profile.

**Ramification:** \{AI05-0239-1\} The parameter and result subtypes are not used in overload resolution. Only type conformance of profiles is considered during overload resolution. Legality rules generally require at least mode conformance in addition, but those rules are not used in overload resolution.
Legality Rules

27/2 \{AI95-00332-01\} When the expected type for a construct is one that requires that its expected type be a single type in a given class, the type of expected for the construct shall be determinable solely from the context in which the construct appears, excluding the construct itself, but using the requirement that it be in the given class. The type of the construct is then this single expected type. Furthermore, the context shall not be one that expects any type in some class that contains types of the given class; in particular, the construct shall not be the operand of a type_conversion.

27.a/2 Ramification: \{AI95-00230-01\} For example, the expected type for a string literal is required to be a single string type. But the expected type for the operand of a type_conversion is any type. Therefore, a string type in scope (which is never the case). The reason for these rules is so that the compiler will not have to search “everywhere” to see if there is exactly one type in a class in scope.

27.b/2 Discussion: \{AI95-00332-01\} The first sentence is carefully worded so that it only mentions “expected type” as part of identifying the interesting case, but doesn't require that the context actually provide such an expected type. This allows such constructs to be used inside of constructs that don't provide an expected type (like qualified expressions and renames). Otherwise, such constructs wouldn't allow aggregates, 'Access, and so on.

27.1/3 \{AI05-0102-1\} \{AI05-0149-1\} \{AI05-0299-1\} Other than for the simple_expression of a membership test, if the expected type for a name or expression is not the same as the actual type of the name or expression, the actual type shall be convertible to the expected type (see 4.6); further, if the expected type is a named access-to-object type with designated type D1 and the actual type is an anonymous access-to-object type with designated type D2, then D1 shall cover D2, and the name or expression shall denote a view with an accessibility level for which the statically deeper relationship applies; in particular it shall not denote an access parameter nor a stand-alone access object.

27.c/3 Reason: This rule prevents an implicit conversion that would be illegal if it was an explicit conversion. For instance, this prevents assigning an access-to-constant value into a stand-alone anonymous access-to-variable object. It also covers convertibility of the designated type and accessibility checks.

27.d/3 The rule also minimizes cases of implicit conversions when the tag check or the accessibility check might fail. We word it this way because access discriminants should also be disallowed if their enclosing object is designated by an access parameter.

27.e/3 Ramification: This rule does not apply to expressions that don't have expected types (such as the operand of a qualified expression or the expression of a renames). We don't need a rule like this in those cases, as the type needs to be the same; there is no implicit conversion.

A complete context shall have at least one acceptable interpretation; if there is exactly one, then that one is chosen.

28.a Ramification: This, and the rule below about ambiguity, are the ones that suck in all the Syntax Rules and Name Resolution Rules as compile-time rules. Note that this and the ambiguity rule have to be Legality Rules.

29 There is a preference for the primitive operators (and ranges) of the root numeric types root_integer and root_real. In particular, if two acceptable interpretations of a constituent of a complete context differ only in that one is for a primitive operator (or range) of the type root_integer or root_real, and the other is not, the interpretation using the primitive operator (or range) of the root numeric type is preferred.

29.a Reason: The reason for this preference is so that expressions involving literals and named numbers can be unambiguous. For example, without the preference rule, the following would be ambiguous:

\[
\begin{align*}
N & \text{ constant } := 123; \\
& \text{ if } N > 100 \text{ then } -- \text{ Preference for root_integer "<=" operator.} \\
& \text{ end if;}
\end{align*}
\]

29.b/1 \{AI05-0149-1\} Similarly, there is a preference for the equality operators of the universal_access type (see 4.5.2). If two acceptable interpretations of a constituent of a complete context differ only in that one is for an equality operator of the universal_access type, and the other is not, the interpretation using the equality operator of the universal_access type is preferred.
Reason: This preference is necessary because of implicit conversion from an anonymous access type to a named access type, which would allow the equality operator of any named access type to be used to compare anonymous access values (and that way lies madness).

For a complete context, if there is exactly one overall acceptable interpretation where each constituent's interpretation is the same as or preferred (in the above sense) over those in all other overall acceptable interpretations, then that one overall acceptable interpretation is chosen. Otherwise, the complete context is ambiguous.

A complete context other than a pragma_argument_association shall not be ambiguous.

A complete context that is a pragma_argument_association is allowed to be ambiguous (unless otherwise specified for the particular pragma), but only if every acceptable interpretation of the pragma argument is as a name that statically denotes a callable entity. Such a name denotes all of the declarations determined by its interpretations, and all of the views declared by these declarations.

Ramification: {AI95-00224-01} {AI05-0229-1} This applies to Inline, Suppress, Import, Export, and Convention pragmas. For example, it is OK to say "pragma Export(C, Entity_Name Suppress(Elaboration_Check_On => P.Q));", even if there are two directly visible P's, and there are two Q's declared in the visible part of each P. In this case, P.Q denotes four different declarations. This rule also applies to certain pragmas defined in the Specialized Needs Annexes. It almost applies to Pure, Elaborate_Body, and Elaborate_All pragmas, but those can't have overloading for other reasons. Note that almost all of these pragmas are obsolescent (see J.10 and J.15), and a major reason is that this rule has proven to be too broad in practice (it is common to want to specify something on a single subprogram of an overloaded set, that can't be done easily with this rule). Aspect Specifications, which are given on individual declarations, are preferred in Ada 2012.

Note that if a pragma argument denotes a call to a callable entity, rather than the entity itself, this exception does not apply, and ambiguity is disallowed.

Note that we need to carefully define which pragma-related rules are Name Resolution Rules, so that, for example, a pragma Inline does not pick up subprograms declared in enclosing declarative regions, and therefore make itself illegal.

We say “statically denotes” in the above rule in order to avoid having to worry about how many times the name is evaluated, in case it denotes more than one callable entity.

NOTES
17 If a usage name has only one acceptable interpretation, then it denotes the corresponding entity. However, this does not mean that the usage name is necessarily legal since other requirements exist which are not considered for overload resolution; for example, the fact that an expression is static, whether an object is constant, mode and subtype conformance rules, freezing rules, order of elaboration, and so on.

Similarly, subtypes are not considered for overload resolution (the violation of a constraint does not make a program illegal but raises an exception during program execution).

Incompatibilities With Ada 83

The new preference rule for operators of root numeric types is upward incompatible, but only in cases that involved Beaujolais effects in Ada 83. Such cases are ambiguous in Ada 95.

Extensions to Ada 83

The rule that allows an expected type to match an actual expression of a universal type, in combination with the new preference rule for operators of root numeric types, subsumes the Ada 83 "implicit conversion" rules for universal types.

Wording Changes from Ada 83

In Ada 83, it is not clear what the “syntax rules” are. A183-00157 states that a certain textual rule is a syntax rule, but it's still not clear how one tells in general which textual rules are syntax rules. We have solved the problem by stating exactly which rules are syntax rules — the ones that appear under the “Syntax” heading.

RM83 has a long list of the “forms” of rules that are to be used in overload resolution (in addition to the syntax rules). It is not clear exactly which rules fall under each form. We have solved the problem by explicitly marking all rules that are used in overload resolution. Thus, the list of kinds of rules is unnecessary. It is replaced with some introductory (intentionally vague) text explaining the basic idea of what sorts of rules are overloading rules.
It is not clear from RM83 what information is embodied in a “meaning” or an “interpretation.” “Meaning” and “interpretation” were intended to be synonymous; we now use the latter only in defining the rules about overload resolution. “Meaning” is used only informally. This subclause attempts to clarify what is meant by “interpretation.”

For example, RM83 does not make it clear that overload resolution is required in order to match subprogram bodies with their corresponding declarations (and even to tell whether a given subprogram body is the completion of a previous declaration). Clearly, the information needed to do this is part of the “interpretation” of a subprogram body. The resolution of such things is defined in terms of the “expected profile” concept. Ada 95 has some new cases where expected profiles are needed — the resolution of P'Access, where P might denote a subprogram, is an example.

RM83-8.7(2) might seem to imply that an interpretation embodies information about what is denoted by each usage name, but not information about which syntactic category each construct belongs to. However, it seems necessary to include such information, since the Ada grammar is highly ambiguous. For example, X(Y) might be a function_call or an indexed_component, and no context-free/syntactic information can tell the difference. It seems like we should view X(Y) as being, for example, “interpreted as a function_call” (if that’s what overload resolution decides it is). Note that there are examples where the denotation of each usage name does not imply the syntactic category. However, even if that were not true, it seems that intuitively, the interpretation includes that information. Here’s an example:

```ada
type T; type A is access T; type T is array(Integer range 1..10) of A;
I : Integer := 3;
function F(X : Integer := 7) return A;
Y : A := F(I); -- Ambiguous? (We hope so.)
```

Consider the declaration of Y (a complete context). In the above example, overload resolution can easily determine the declaration, and therefore the entity, denoted by Y, A, F, and I. However, given all of that information, we still don’t know whether F(I) is a function_call or an indexed_component whose prefix is a function_call. (In the latter case, it is equivalent to F(7).all[1]).

It seems clear that the declaration of Y ought to be considered ambiguous. We describe that by saying that there are two interpretations, one as a function_call, and one as an indexed_component. These interpretations are both acceptable to the overloading rules. Therefore, the complete context is ambiguous, and therefore illegal.

It is the intent that the Ada 95 preference rule for root numeric operators is more locally enforceable than that of RM83-4.6(15). It should also eliminate interpretation shifts due to the addition or removal of a use_clause (the so-called Beaujolais effect).

RM83-8.7 seems to be missing some complete contexts, such as pragma_argument_associations, declarative_items that are not declarations or aspect_clause_representation_clauses, and context_items. We have added these, and also replaced the “must be determinable” wording of RM83-5.4(3) with the notion that the expression of a case_statement is a complete context.

Cases like the Val attribute are now handled using the normal type resolution rules, instead of having special cases that explicitly allow things like “any integer type.”

**Incompatibilities With Ada 95**

Ada 95 allowed name resolution to distinguish between anonymous access-to-variable and access-to-constant types. This is similar to distinguishing between subprograms with in and in out parameters, which is known to be bad. Thus, that part of the rule was dropped as we now have anonymous access-to-constant types, making this much more likely.

```ada
type Cacc is access constant Integer;
procedure Proc (Acc : access Integer) ...
procedure Proc (Acc : Cacc) ...
List : Cacc := ...; Proc (List); -- OK in Ada 95, ambiguous in Ada 2005.
```

If there is any code like this (such code should be rare), it will be ambiguous in Ada 2005.

**Extensions to Ada 95**

Generalized the anonymous access resolution rules to support the new capabilities of anonymous access types (that is, access-to-subprogram and access-to-constant).

We now allow the creation of self-referencing types via anonymous access types. This is an extension in unusual cases involving task and protected types. For example:

```ada
task type T;
```
Wording Changes from Ada 95

{AI95-00332-01} Corrected the “single expected type” so that it works in contexts that don’t have expected types (like object renames and qualified expressions). This fixes a hole in Ada 95 that appears to prohibit using aggregates, 'Access, character literals, string literals, and allocators in qualified expressions.

Incompatibilities With Ada 2005

{AI05-0149-1} Implicit conversion is now allowed from anonymous access-to-object types to general access-to-object types. Such conversions can make calls ambiguous. That can only happen when there are two visible subprograms with the same name and have profiles that differ only by a parameter that is of a named or anonymous access type, and the actual argument is of an anonymous access type. This should be rare, as many possible calls would be ambiguous even in Ada 2005 (including allocators and any actual of a named access type if the designated types are the same).

Extensions to Ada 2005

{AI05-0149-1} Implicit conversion is allowed from anonymous access-to-object types to general access-to-object types if the designated type is convertible and runtime checks are minimized. See also the incompatibilities section.

Wording Changes from Ada 2005

{AI05-0102-1} Added a requirement here that implicit conversions are convertible to the appropriate type. This rule was scattered about the Standard, we moved a single generalized version here.
9 Tasks and Synchronization

\{AI05-0299-1\} The execution of an Ada program consists of the execution of one or more tasks. Each task represents a separate thread of control that proceeds independently and concurrently between the points where it interacts with other tasks. The various forms of task interaction are described in this clause, and include:

- the activation and termination of a task;
- a call on a protected subprogram of a protected object, providing exclusive read-write access, or concurrent read-only access to shared data;
- a call on an entry, either of another task, allowing for synchronous communication with that task, or of a protected object, allowing for asynchronous communication with one or more other tasks using that same protected object;
- a timed operation, including a simple delay statement, a timed entry call or accept, or a timed asynchronous select statement (see next item);
- an asynchronous transfer of control as part of an asynchronous select statement, where a task stops what it is doing and begins execution at a different point in response to the completion of an entry call or the expiration of a delay;
- an abort statement, allowing one task to cause the termination of another task.

To be honest: The execution of an Ada program consists of the execution of one or more partitions (see 10.2), each of which in turn consists of the execution of an environment task and zero or more subtasks.

In addition, tasks can communicate indirectly by reading and updating (unprotected) shared variables, presuming the access is properly synchronized through some other kind of task interaction.

Static Semantics

The properties of a task are defined by a corresponding task declaration and task_body, which together define a program unit called a task unit.

Dynamic Semantics

Over time, tasks proceed through various states. A task is initially inactive; upon activation, and prior to its termination it is either blocked (as part of some task interaction) or ready to run. While ready, a task competes for the available execution resources that it requires to run.

Discussion: \{AI05-0229-1\} The means for selecting which of the ready tasks to run, given the currently available execution resources, is determined by the task dispatching policy in effect, which is generally implementation defined, but may be controlled by aspects, pragmas, and operations defined in the Real-Time Annex (see D.2 and D.5).

NOTES

1 Concurrent task execution may be implemented on multicomputers, multiprocessors, or with interleaved execution on a single physical processor. On the other hand, whenever an implementation can determine that the required semantic effects can be achieved when parts of the execution of a given task are performed by different physical processors acting in parallel, it may choose to perform them in this way.

Wording Changes from Ada 83

The introduction has been rewritten.

We use the term "concurrent" rather than "parallel" when talking about logically independent execution of threads of control. The term "parallel" is reserved for referring to the situation where multiple physical processors run simultaneously.
9.1 Task Units and Task Objects

A task unit is declared by a task declaration, which has a corresponding task body. A task declaration may be a task_type_declaration, in which case it declares a named task type; alternatively, it may be a single_task_declaration, in which case it defines an anonymous task type, as well as declaring a named task object of that type.

Syntax

```
{AI95-00345-01} {AI05-0183-1} task_type_declaration ::= task_type defining_identifier [known_discriminant_part]
____ [aspect_specification] [is
____ [new interface_list with] _task_definition];

{AI95-00399-01} {AI05-0183-1} single_task_declaration ::= task defining_identifier
____ [aspect_specification] [is
____ [new interface_list with] _task_definition];

task_definition ::= {task_item}
[ private
 {task_item} ]
end [task_identifier]

{8652/0009} {AI95-00137-01} task_item ::= entry_declaration | aspect_clause representation_clause

{AI05-0267-1} task_body ::= task_body defining_identifier
____ [aspect_specification] is declarative_part
begin
 handled_sequence_of_statements
end [task_identifier];
```

If a task_identifier appears at the end of a task_definition or task_body, it shall repeat the defining_identifier.

Legality Rules

```
{AI95-00345-01} A task declaration requires a completion, which shall be a task_body, and every task_body shall be the completion of some task declaration.

This paragraph was deleted. To be honest: The completion can be a pragma Import, if the implementation supports it.

Paragraph 8 was deleted.
```

Static Semantics

```
A task_definition defines a task type and its first subtype. The first list of task_items of a task_definition, together with the known_discriminant_part, if any, is called the visible part of the task unit. [ The optional list of task_items after the reserved word private is called the private part of the task unit.]

Proof: {AI05-0299-1} Private part is defined in Clause Section 8.
```
For a task declaration without a task_definition, a task_definition without task_items is assumed.

For a task declaration with an interface_list, the task_type inherits user-defined primitive subprograms from each progenitor type (see 3.9.4), in the same way that a derived_type inherits user-defined primitive subprograms from its progenitor types (see 3.4). If the first parameter of a primitive inherited subprogram is of the task_type or an access parameter designating the task_type, and there is an entry_declaration for a single entry with the same identifier within the task declaration, whose profile is type conformant with the prefixed view profile of the inherited subprogram, the inherited subprogram is said to be implemented by the conforming task_entry using an implicitly declared nonabstract subprogram which has the same profile as the inherited subprogram and which overrides it.

**Ramification:** The inherited subprograms can only come from an interface given as part of the task declaration.

**Reason:** The part about the implicitly declared subprogram is needed so that a subprogram implemented by an entry is considered to be overridden for the purpose of the other rules of the language. Without it, it would for instance be illegal for an abstract subprogram to be implemented by an entry, because the abstract subprogram would not be overridden. The Legality Rules below ensure that there is no conflict between the implicit overriding subprogram and a user-defined overriding subprogram.

**Legality Rules**

A task_declaration requires a completion[, which shall be a task_body,] and every task_body shall be the completion of some task_declaration.

To be honest: If the completion can be a pragma Import, if the implementation supports it, the task_body can be imported (using aspect Import, see B.1), in which case no explicit task_body is allowed.

Each interface_subtype_mark of an interface_list appearing within a task declaration shall denote a limited interface_type that is not a protected interface.

**Proof:** 3.9.4 requires that an interface_list only name interface_types, and limits the descendants of the various kinds of interface_types. Only a limited, task, or synchronized interface can have a task_type descendant. Nonlimited or protected interfaces are not allowed, as they offer operations that a task does not have.

The prefixed view profile of an explicitly declared primitive subprogram of a tagged task_type shall not be type conformant with any entry of the task_type, if the subprogram has the same defining name as the entry and the first parameter of the subprogram is of the task_type or is an access parameter designating the task_type.

**Reason:** This prevents the existence of two operations with the same name and profile which could be called with a prefixed view. If the operation was inherited, this would be illegal by the following rules; this rule puts inherited and noninherited routines on the same footing. Note that this only applies to tagged task types (that is, those with an interface in their declaration); we do that as there is no problem with prefixed view calls of primitive operations for "normal" task types, and having this rule apply to all tasks would be incompatible with Ada 95.

For each primitive subprogram inherited by the type declared by a task declaration, at most one of the following shall apply:

- the inherited subprogram is overridden with a primitive subprogram of the task type, in which case the overriding subprogram shall be subtype conformant with the inherited subprogram and not abstract; or
- the inherited subprogram is implemented by a single entry of the task type; in which case its prefixed view profile shall be subtype conformant with that of the task_entry.

**Ramification:** An entry may implement two subprograms from the ancestors, one whose first parameter is of type T and one whose first parameter is of type access T. That doesn't cause implementation problems because “implemented by” (unlike “overridden”) probably entails the creation of wrappers.
9.1 Task Units and Task Objects

9.9/2 If neither applies, the inherited subprogram shall be a null procedure. In addition to the places where
Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a
generic unit.

9.9/2 Reason: Each inherited subprogram can only have a single implementation (either from overriding a subprogram or
implementing an entry), and must have an implementation unless the subprogram is a null procedure.

Dynamic Semantics

10 [ The elaboration of a task declaration elaborates the task_definition. The elaboration of a single_task_
declaration also creates an object of an (anonymous) task type.]

10.a Proof: This is redundant with the general rules for the elaboration of a full_type_declaration and an
object_declaration.

11 [The elaboration of a task_definition creates the task type and its first subtype;] it also includes the
elaboration of the entry_declarations in the given order.

12a/1 {8652/0009} {AI95-00137-01} As part of the initialization of a task object, any
aspect_clause, representation_clause, and any per-object constraints associated with entry_
declarations of the corresponding task_definition are elaborated in the given order.

12a.1 Reason: The only aspect_clause, representation_clause, defined for task entries are ones that specify the Address of
an entry, as part of defining an interrupt entry. These clearly need to be elaborated per-object, not per-type. Normally
the address will be a function of a discriminant, if such an Address clause is in a task type rather than a single task
declaration, though it could rely on a parameterless function that allocates sequential interrupt vectors.

We do not mention representation pragmas, since each pragma may have its own elaboration rules.

13 The elaboration of a task_body has no effect other than to establish that tasks of the type can from then
on be activated without failing the Elaboration_Check.

14 [The execution of a task_body is invoked by the activation of a task of the corresponding type (see 9.2).]

The content of a task object of a given task type includes:

16 • The values of the discriminants of the task object, if any;
17 • An entry queue for each entry of the task object;
17.a Ramification: "For each entry" implies one queue for each single entry, plus one for each entry of each entry family.
18 • A representation of the state of the associated task.

NOTES

19/2 2 {AI95-00382-01} Other than in an access_definition, the name of a task unit within
the declaration or body of
the task unit, the name of the task unit denotes the current instance of the unit (see 8.6), rather than the first subtype of the
corresponding task type (and thus the name cannot be used as a subtype_mark).

19.a/2 Discussion: {AI95-00382-01} It can be used as a subtype_mark in an anonymous access type. In addition
However, it is possible to refer to some other subtype of the task type within its body, presuming such a subtype has been declared
between the task_type_declaration and the task_body.

3 The notation of a selected_component can be used to denote a discriminant of a task (see 4.1.3). Within a task unit, the
name of a discriminant of the task type denotes the corresponding discriminant of the current instance of the unit.

21/2 4 {AI95-00287-01} A task type is a limited type (see 7.5), and hence precludes use of assignment_statements and
predefined equality operators. If an application needs to store and exchange task
identities, it can do so by defining an access type designating the corresponding task objects and by using access values for
identification purposes. Assignment is available for such an access type as for any access type. Alternatively, if the
implementation supports the Systems Programming Annex, the Identity attribute can be used for task identification (see
C.7.1(3)).
Examples

Examples of declarations of task types:

```ada
task type Server is
  entry Next_Work_Item(WI : in Work_Item);
  entry Shut_Down;
end Server;
{AI95-00433-01} task type Keyboard_Driver(ID : Keyboard_ID := New_ID) is
  new Serial_Device with -- see 3.9.4
  entry Read (C : out Character);
  entry Write(C : in  Character);
end Keyboard_Driver;
```

Examples of declarations of single tasks:

```ada
task Controller is
  entry Request(Level)(D : Item); -- a family of entries
end Controller;

task Parser is
  entry Next_Lexeme(L : in Lexical_Element);
  entry Next_Action(A : out Parser_Action);
end;

task User; -- has no entries
```

Examples of task objects:

```ada
Agent : Server;
Teletype : Keyboard_Driver(TTY_ID);
Pool : array(1 .. 10) of Keyboard_Driver;
```

Example of access type designating task objects:

```ada
type Keyboard is access Keyboard_Driver;
Terminal : Keyboard := new Keyboard_Driver(Term_ID);
```

Extensions to Ada 83

The syntax rules for task declarations are modified to allow a known_discriminant_part, and to allow a private part. They are also modified to allow entry_declarations and aspect_clause,representation_clauses to be mixed.

Wording Changes from Ada 83

The syntax rules for tasks have been split up according to task types and single tasks. In particular: The syntax rules for task_declaration and task_specification are removed. The syntax rules for task_type_declaration, single_task_declaration, task_definition and task_item are new. The syntax rule for task_body now uses the nonterminal handled_sequence_of_statements. The declarative_part of a task_body is now required; that doesn't make any real difference, because a declarative_part can be empty.

Extensions to Ada 95

{AI95-00345-01} {AI95-00397-01} {AI95-00399-01} {AI95-00419-01} Task types and single tasks can be derived from one or more interfaces. Entries of the task type can implement the primitive operations of an interface. Overriding indicators can be used to specify whether or not an entry implements a primitive operation.

Wording Changes from Ada 95

{8652/0029} {AI95-00116-01} **Corrigendum:** Clarified that a task type has an implicit empty task_definition if none is given.

{8652/0009} {AI95-00137-01} **Corrigendum:** Changed representation clauses to aspect clauses to reflect that they are used for more than just representation.

{AI95-00287-01} Revised the note on operations of task types to reflect that limited types do have an assignment operation, but not copying (assignment statements).
9.2 Task Execution - Task Activation

Dynamic Semantics

The execution of a task of a given task type consists of the execution of the corresponding task_body. The initial part of this execution is called the activation of the task; it consists of the elaboration of the declarative_part of the task_body. Should an exception be propagated by the elaboration of its declarative_part, the activation of the task is defined to have failed, and it becomes a completed task.

A task object (which represents one task) can be a part of a stand-alone object, of an object created by either, as part of the elaboration of an object_declaration occurring immediately within some declarative region, or as part of the evaluation of an allocator, or of an anonymous object of a limited type, or a coextension of one of these. All tasks that are part or coextensions of any of the stand-alone_objects created by the elaboration of object_declarations (or generic associations of formal objects of mode in) of a single declarative region (including subcomponents of the declared objects) are activated together. All tasks that are part or coextensions of a single object that is not a stand-alone object are activated together. Similarly, all tasks created by the evaluation of a single allocator are activated together. The activation of a task is associated with the innermost allocator or object_declaration that is responsible for its creation.

Discussion: The initialization of an object_declaration or allocator can indirectly include the creation of other objects that contain tasks. For example, the default expression for a subcomponent of an object created by an allocator might call a function that evaluates a completely different allocator. Tasks created by the two allocators are not activated together.

Ramification: If Tasking_Error is raised, it can be handled by handlers of the handled_sequence_of_statements.

For tasks that are part or coextensions of a single object that is not a stand-alone object, activations are initiated after completing any initialization of the outermost object enclosing these tasks, prior to performing any other operation on the outermost object. In particular, for tasks that are part or coextensions of the object created by the evaluation of an allocator, the activations are initiated as the last step of evaluating the allocator, after completing any initialization for the object created by the allocator, and prior to returning the new access value. For tasks that are part or coextensions of an object that is the result of a function call, the activations are not initiated until after the function returns.

Discussion: The intent is that “temporary” objects with task parts (or coextensions) are treated similarly to an object created by an allocator. The “whole” object is initialized, and then all of the task parts (including

Extensions to Ada 2005

An optional aspect_specification can be used in a task_type_declaration, a single_task_declaration, and a task_body. This is described in 13.1.1.

Wording Changes from Ada 2005

Correction: Clarified that an inherited procedure of a progenitor is overridden when it is implemented by an entry.

Correction: Added the missing defining name in the no conflicting primitive operation rule.
the coextensions) are activated together. Each such “whole” object has its own task activation sequence, involving the activating task being suspended until all the new tasks complete their activation.

The task that created the new tasks and initiated their activations (the activator) is blocked until all of these activations complete (successfully or not). Once all of these activations are complete, if the activation of any of the tasks has failed [(due to the propagation of an exception)], Tasking_Error is raised in the activator, at the place at which it initiated the activations. Otherwise, the activator proceeds with its execution normally. Any tasks that are aborted prior to completing their activation are ignored when determining whether to raise Tasking_Error.

**Ramification:** Note that a task created by an allocator does not necessarily depend on its activator; in such a case the activator's termination can precede the termination of the newly created task.

**Discussion:** Tasking_Error is raised only once, even if two or more of the tasks being activated fail their activation.

**To be honest:** [AI95-00265-01] The pragma Partition Elaboration Policy (see H.6) can be used to defer task activation to a later point, thus changing many of these rules.

{AI05-0045-1} If the master that directly encloses the point where the activation of a task \( T \) would be initiated, completes before the activation of \( T \) is initiated, \( T \) becomes terminated and is never activated. Furthermore, if a return statement is left such that the return object is not returned to the caller, any task that was created as a part of the return object or one of its coextensions immediately becomes Should the task that created the new tasks never reach the point where it would initiate the activations (due to an abort or the raising of an exception), the newly created tasks become terminated and are never activated.

**Ramification:** {AI05-0045-1} The first case can only happen if the activation point of \( T \) is not reached due to an exception being raised or a task or statement being aborted. Note that this is exclusive; if the master completes normally and starts finalization, we're already past the activation point.

{AI05-0045-1} The second case can happen with an exception being raised in a return statement, by an exit or goto from an extended return statement, or by a return statement being aborted. Any tasks created for the return object of such a return statement are never activated.

**NOTES**

5 An entry of a task can be called before the task has been activated.

6 If several tasks are activated together, the execution of any of these tasks need not await the end of the activation of the other tasks.

7 A task can become completed during its activation either because of an exception or because it is aborted (see 9.8).

**Examples**

**Example of task activation:**

```ada
procedure P is
   A, B : Server;    -- elaborate the task objects A, B
   C    : Server;    -- elaborate the task object C
begin
   -- the tasks A, B, C are activated together before the first statement
   ...
end;
```

**Wording Changes from Ada 83**

We have replaced the term suspended with blocked, since we didn't want to consider a task blocked when it was simply competing for execution resources. "Suspended" is sometimes used more generally to refer to tasks that are not actually running on some processor, due to the lack of resources.

{AI05-0299-1} This subclause has been rewritten in an attempt to improve presentation.

**Wording Changes from Ada 95**

{AI95-00416-01} Adjusted the wording for activating tasks to handle the case of anonymous function return objects. This is critical; we don't want to be waiting for the tasks in a return object when we exit the function normally.
9.3 Task Dependence - Termination of Tasks

Dynamic Semantics

Each task (other than an environment task — see 10.2) depends on one or more masters (see 7.6.1), as follows:

- If the task is created by the evaluation of an allocator for a given access type, it depends on each master that includes the elaboration of the declaration of the ultimate ancestor of the given access type.
- If the task is created by the elaboration of an object_declaration, it depends on each master that includes this elaboration.
- Otherwise, the task depends on the master of the outermost object of which it is a part (as determined by the accessibility level of that object — see 3.10.2 and 7.6.1), as well as on any master whose execution includes that of the master of the outermost object.

Furthermore, if a task depends on a given master, it is defined to depend on the task that executes the master, and (recursively) on any master of that task.

Discussion: Don’t confuse these kinds of dependences with the dependences among compilation units defined in 10.1.1, “Compilation Units - Library Units”.

A task is said to be completed when the execution of its corresponding task_body is completed. A task is said to be terminated when any finalization of the task_body has been performed (see 7.6.1). [The first step of finalizing a master (including a task_body) is to wait for the termination of any tasks dependent on the master.] The task executing the master is blocked until all the dependents have terminated. [Any remaining finalization is then performed and the master is left.]

Completion of a task (and the corresponding task_body) can occur when the task is blocked at a select_statement with an open terminate_alternative (see 9.7.1); the open terminate_alternative is selected if and only if the following conditions are satisfied:

- The task depends on some completed master; and
- Each task that depends on the master considered is either already terminated or similarly blocked at a select_statement with an open terminate_alternative.

When both conditions are satisfied, the task considered becomes completed, together with all tasks that depend on the master considered that are not yet completed.

Ramification: Any required finalization is performed after the selection of terminate_alternatives. The tasks are not callable during the finalization. In some ways it is as though they were aborted.

NOTES

8 The full view of a limited private type can be a task type, or can have subcomponents of a task type. Creation of an object of such a type creates dependences according to the full type.
9 An object_renaming_declaration defines a new view of an existing entity and hence creates no further dependence.
10 The rules given for the collective completion of a group of tasks all blocked on select_statements with open terminate_alternatives ensure that the collective completion can occur only when there are no remaining active tasks that could call one of the tasks being collectively completed.
11 If two or more tasks are blocked on `select_statement`s with open `terminate_alternative`s, and become completed collectively, their finalization actions proceed concurrently.

12 The completion of a task can occur due to any of the following:

- the raising of an exception during the elaboration of the `declarative_part` of the corresponding `task_body`;
- the completion of the `handled_sequence_of_statements` of the corresponding `task_body`;
- the selection of an open `terminate_alternative` of a `select_statement` in the corresponding `task_body`;
- the abort of the task.

Example of task dependence:

```adala
declare
  type Global is access Server;  -- see 9.1
  A, B : Server;
  G    : Global;
begin
  -- activation of A and B
  declare
    type Local is access Server;
    X : Global := new Server;  -- activation of X.all
    L : Local := new Server;   -- activation of L.all
    C : Server;
  begin
    -- activation of C
    G := X;  -- both G and X designate the same task object
    ...
  end;  -- await termination of C and L.all (but not X.all)
  ...
end;  -- await termination of A, B, and G.all
```

Wording Changes from Ada 83

We have revised the wording to be consistent with the definition of master now given in 7.6.1, “Completion and Finalization”.

Tasks that used to depend on library packages in Ada 83, now depend on the (implicit) `task_body` of the environment task (see 10.2). Therefore, the environment task has to wait for them before performing library level finalization and terminating the partition. In Ada 83 the requirement to wait for tasks that depended on library packages was not as clear.

What was "collective termination" is now "collective completion" resulting from selecting `terminate_alternative`s. This is because finalization still occurs for such tasks, and this happens after selecting the `terminate_alternative`, but before termination.

Wording Changes from Ada 95

{AI95-00416-01} Added missing wording that explained the master of tasks that are neither object declarations nor allocators, such as function returns.

9.4 Protected Units and Protected Objects

A `protected object` provides coordinated access to shared data, through calls on its visible `protected operations`, which can be `protected subprograms` or `protected entries`. A `protected unit` is declared by a `protected declaration`, which has a corresponding `protected_body`. A protected declaration may be a `protected_type_declaration`, in which case it declares a named protected type; alternatively, it may be a `single_protected_declaration`, in which case it defines an anonymous protected type, as well as declaring a named protected object of that type.
9.4 Protected Units and Protected Objects

Syntax

```ada
{AI95-00399-01} {AI05-0183-1} protected_type_declaration ::= protected type defining_identifier [known_discriminant_part]
    [aspect_specification] is
    [new interface_list with]
    protected_definition;

{AI95-00345-01} {AI05-0183-1} single_protected_declaration ::= protected defining_identifier
    [aspect_specification] is
    [new interface_list with]
    protected_definition;

protected_definition ::= { protected_operation_declaration }
    [private
    { protected_element_declaration } ]
end [protected_identifier]

protected_operation_declaration ::= subprogram_declaration
    | entry_declaration
    | aspect_clause
    | representation_clause

protected_element_declaration ::= protected_operation_declaration
    | component_declaration

Reason: We allow the operations and components to be mixed because that's how other things work (for example, package declarations). We have relaxed the ordering rules for the items inside declarative_parts and task_definitions as well.

If a protected_identifier appears at the end of a protected_definition or protected_body, it shall repeat the defining_identifier.

Legality Rules

A protected declaration requires a completion[which shall be a protected_body] and every protected_body shall be the completion of some protected declaration.

This paragraph was deleted. To be honest: The completion can be a pragma Import, if the implementation supports it.

Paragraph 10 was deleted.

Static Semantics

A protected_definition defines a protected type and its first subtype. The list of protected_operation_declarations of a protected_definition, together with the known_discriminant_part, if any, is called the visible part of the protected unit. [The optional list of protected_element_declarations after the reserved word private is called the private part of the protected unit.]

Proof: {AI05-0299-1} Private part is defined in ClauseSection 8.
For a protected declaration with an interface list, the protected type inherits user-defined primitive subprograms from each progenitor type (see 3.9.4), in the same way that a derived type inherits user-defined primitive subprograms from its progenitor types (see 3.4). If the first parameter of a primitive inherited subprogram is of the protected type or an access parameter designating the protected type, and there is a protected operation declaration for a protected subprogram or single entry with the same identifier within the protected declaration, whose profile is type conformant with the prefixed view profile of the inherited subprogram, the inherited subprogram is said to be implemented by the conforming protected subprogram or entry using an implicitly declared nonabstract subprogram which has the same profile as the inherited subprogram and which overrides it.

Ramification: The inherited subprograms can only come from an interface given as part of the protected declaration.

Reason: The part about the implicitly declared subprogram is needed so that a subprogram implemented by an entry or subprogram is considered to be overridden for the purpose of the other rules of the language. Without it, it would for instance be illegal for an abstract subprogram to be implemented by an entry, because the abstract subprogram would not be overridden. The Legality Rules below ensure that there is no conflict between the implicit overriding subprogram and a user-defined overriding subprogram.

Legality Rules

A protected declaration requires a completion, which shall be a protected body, and every protected body shall be the completion of some protected declaration.

Proof: 3.9.4 requires that an interface list only name interface types, and limits the descendants of the various kinds of interface types. Only a limited, protected, or synchronized interface can have a protected type descendant. Nonlimited or task interfaces are not allowed, as they offer operations that a protected type does not have.

The prefixed view profile of an explicitly declared primitive subprogram of a tagged protected type shall not be type conformant with any protected operation of the protected type, if the subprogram has the same defining name as the protected operation and the first parameter of the subprogram is of the protected type or is an access parameter designating the protected type.

Reason: This prevents the existence of two operations with the same name and profile which could be called with a prefixed view. If the operation was inherited, this would be illegal by the following rules; this rule puts inherited and noninherited routines on the same footing. Note that this only applies to tagged protected types (that is, those with an interface in their declaration); we do that as there is no problem with prefixed view calls of primitive operations for "normal" protected types, and having this rule apply to all protected types would be incompatible with Ada 95.

For each primitive subprogram inherited by the type declared by a protected declaration, at most one of the following shall apply:

- the inherited subprogram is overridden with a primitive subprogram of the protected type, in which case the overriding subprogram shall be subtype conformant with the inherited subprogram and not abstract; or

- the inherited subprogram is implemented by a protected subprogram or single entry of the protected type, in which case its prefixed view profile shall be subtype conformant with that of the protected subprogram or entry.

If neither applies, the inherited subprogram shall be a null procedure. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit.
Reason: Each inherited subprogram can only have a single implementation (either from overriding a subprogram, implementing a subprogram, or implementing an entry), and must have an implementation unless the subprogram is a null procedure.

{AI95-00345-01} {AI05-0291-1} If an inherited subprogram is implemented by a protected procedure or an entry, then the first parameter of the inherited subprogram shall be of mode **out** or **in out**, or an access-to-variable parameter. If an inherited subprogram is implemented by a protected function, then the first parameter of the inherited subprogram shall be of mode **in**, but not an access-to-variable parameter.

Reason: For a protected procedure or entry, the protected object can be read or written (see 9.5.1). A subprogram that is implemented by a protected procedure or entry must have a profile which reflects that in order to avoid confusion. Similarly, a protected function has a parameter that is a constant, and the inherited routine should reflect that.

{AI95-00397-01} If a protected subprogram declaration has an **overriding_indicator**, then at the point of the declaration:

- if the **overriding_indicator** is **overriding**, then the subprogram shall implement an inherited subprogram;
- if the **overriding_indicator** is **not overriding**, then the subprogram shall not implement any inherited subprogram.

In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit.

Discussion: These rules are subtly different than those for subprograms (see 8.3.1) because there cannot be “late” inheritance of primitives from interfaces. Hidden (that is, private) interfaces are prohibited explicitly (see 7.3), as are hidden primitive operations (as private operations of public abstract types are prohibited — see 3.9.3).

**Dynamic Semantics**

[The elaboration of a protected declaration elaborates the **protected_definition**. The elaboration of a **single_protected_declaration** also creates an object of an (anonymous) protected type.]

Proof: This is redundant with the general rules for the elaboration of a **full_type_declaration** and an **object_declaration**.

[The elaboration of a **protected_definition** creates the protected type and its first subtype; it also includes the elaboration of the **component_declarations** and **protected_operation_declarations** in the given order.]

[As part of the initialization of a protected object, any per-object constraints (see 3.8) are elaborated.]

Discussion: We do not mention pragmas since each pragma has its own elaboration rules.

The elaboration of a **protected_body** has no other effect than to establish that protected operations of the type can from then on be called without failing the Elaboration_Check.

The content of an object of a given protected type includes:

- The values of the components of the protected object, including (implicitly) an entry queue for each entry declared for the protected object;

  Ramification: "For each entry" implies one queue for each single entry, plus one for each entry of each entry family.

- A representation of the state of the execution resource **associated** with the protected object (one such resource is associated with each protected object).

[The execution resource associated with a protected object has to be acquired to read or update any components of the protected object; it can be acquired (as part of a protected action — see 9.5.1) either for concurrent read-only access, or for exclusive read-write access.]

As the first step of the **finalization** of a protected object, each call remaining on any entry queue of the object is removed from its queue and Program_Error is raised at the place of the corresponding **entry_call_statement**.
**Reason:** This is analogous to the raising of Tasking_Error in callers of a task that completes before accepting the calls. This situation can only occur due to a requeue (ignoring premature unchecked_deallocation), since any task that has accessibility to a protected object is awaited before finalizing the protected object. For example:

```ada
procedure Main is
  task T is
    entry E;
  end T;

  task body T is
    protected PO is
      entry Ee;
    end PO;

    protected body PO is
      entry Ee when False is
        begin
          null;
        end Ee;
    end PO;
    begin
      accept E do
        requeue PO.Ee;
      end E;
    begin
      T.E;
    end Main;

{AI05-0005-1} The environment task is queued on PO.Ee when PO is finalized.
```

In a real example, a server task might park callers on a local protected object for some useful purpose, so we didn't want to disallow this case.

**Bounded (Run-Time) Errors**

{AI95-00280-01} It is a bounded error to call an entry or subprogram of a protected object after that object is finalized. If the error is detected, Program_Error is raised. Otherwise, the call proceeds normally, which may leave a task queued forever.

**Reason:** This is very similar to the finalization rule. It is a bounded error so that an implementation can avoid the overhead of the check if it can ensure that the call still will operate properly. Such an implementation cannot need to return resources (such as locks) to an executive that it needs to execute calls.

This case can happen (and has happened in production code) when a protected object is accessed from the Finalize routine of a type. For example:

```ada
with Ada.Finalization.Controlled;
package Window_Manager is
  type Root Window is new Ada.Finalization.Controlled with private;
  type Any Window is access all Root Window;

  private
    procedure Finalize (Object : in out Root Window);
  end Window_Manager;

package body Window_Manager is
  protected type Lock is
    entry Get_Lock;
    procedure Free_Lock;
  end Lock;

  Window Lock : Lock;

  procedure Finalize (Object : in out Root Window) is
    begin
      Window Lock.Get_Lock;
      Window Lock.Free_Lock;
      Window Lock.Finalize;
      A Window := new Root Window;
    end Window Manager;
```

The environment task will call Window_Lock for the object allocated for A_Window when the collection for Any_Window is finalized, which will happen after the finalization of Window_Lock (because finalization of the package body will occur before that of the package specification).

NOTES

13 {AI95-00382-01} Within the declaration or body of a protected unit other than an access_definition, the name of the protected unit denotes the current instance of the unit (see 8.6), rather than the first subtype of the corresponding protected type (and thus the name cannot be used as a subtype_mark).

Discussion: {AI95-00382-01} It can be used as a subtype_mark in an anonymous access type. In addition, however, it is possible to refer to some other subtype of the protected type within its body, presuming such a subtype has been declared between the protected_type_declaration and the protected_body.

14 A selected_component can be used to denote a discriminant of a protected object (see 4.1.3). Within a protected unit, the name of a discriminant of the protected type denotes the corresponding discriminant of the current instance of the unit.

15 {AI95-00287-01} A protected type is a limited type (see 7.5), and hence precludes use of assignment_statements and has neither an assignment_operation nor predefined equality operators.

16 The bodies of the protected operations given in the protected_body define the actions that take place upon calls to the protected operations.

17 The declarations in the private part are only visible within the private part and the body of the protected unit.

Reason: Component_declarations are disallowed in a protected_body because, for efficiency, we wish to allow the compiler to determine the size of protected objects (when not dynamic); the compiler cannot necessarily see the body. Furthermore, the semantics of initialization of such objects would be problematic — we do not wish to give protected objects object initialization semantics similar to task activation.

The same applies to entry_declarations, since an entry involves an implicit component — the entry queue.

Example of declaration of protected type and corresponding body:

```ada
protected type Resource is
    entry Seize;
    procedure Release;
private
    Busy : Boolean := False;
end Resource;

protected body Resource is
    entry Seize when not Busy is
    begin
        Busy := True;
    end Seize;
    procedure Release is
    begin
        Busy := False;
    end Release;
end Resource;
```

Example of a single protected declaration and corresponding body:

```ada
protected Shared_Array is
    -- Index, Item, and Item_Array are global types
    function Component (N : in Index) return Item;
    procedure Set_Component(N : in Index; E : in Item);
private
    Table : Item_Array(Index) := (others => Null_Item);
end Shared_Array;

protected body Shared_Array is
    function Component (N : in Index) return Item is
    begin
        return Table(N);
    end Component;
```
procedure Set_Component(N : in Index; E : in Item) is
begin
  Table(N) := E;
end Set_Component;
end Shared_Array;

Examples of protected objects:
Control  : Resource;
Flags    : array(1 .. 100) of Resource;

Extensions to Ada 83
{AI05-0299-1} This entire subclause is new; protected units do not exist in Ada 83.

Extensions to Ada 95
{AI95-00345-01} {AI95-00397-01} {AI95-00399-01} {AI95-00401-01} {AI95-00419-01} Protected types and single protected objects can be derived from one or more interfaces. Operations declared in the protected type can implement the primitive operations of an interface. Overriding indicators can be used to specify whether or not a protected operation implements a primitive operation.

Wording Changes from Ada 95
{8652/0009} {AI95-00137-01} Corrigendum: Changed representation clauses to aspect clauses to reflect that they are used for more than just representation.
{AI95-00280-01} Described what happens when an operation of a finalized protected object is called.
{AI95-00287-01} Revised the note on operations of protected types to reflect that limited types do have an assignment operation, but not copying (assignment statements).
{AI95-00382-01} Revised the note on use of the name of a protected type within itself to reflect the exception for anonymous access types.

Incompatibilities With Ada 2005
{AI05-0291-1} When an inherited subprogram is implemented by a protected function, the first parameter has to be an in parameter, but not an access-to-variable type. Ada 2005 allowed access-to-variable parameters in this case; the parameter will need to be changed to access-to-constant with the addition of the constant keyword.

Extensions to Ada 2005
{AI05-0183-1} {AI05-0267-1} An optional aspect_specification can be used in a protected_type_declaration, a single_protected_declaration, and a protected_body. This is described in 13.1.1.

Wording Changes from Ada 2005
{AI05-0042-1} Correction: Clarified that an inherited subprogram of a progenitor is overridden when it is implemented by an entry or subprogram.
{AI05-0090-1} Correction: Added the missing defining name in the no conflicting primitive operation rule.

9.5 Intertask Communication
The primary means for intertask communication is provided by calls on entries and protected subprograms. Calls on protected subprograms allow coordinated access to shared data objects. Entry calls allow for blocking the caller until a given condition is satisfied (namely, that the corresponding entry is open — see 9.5.3), and then communicating data or control information directly with another task or indirectly via a shared protected object.

Static Semantics
{AI05-0225-1} {AI05-0291-1} When a name or prefix denotes any call on an entry, or on a protected subprogram, or a prefixed view of a primitive subprogram of a limited interface whose first parameter is a controlling parameter, the name or prefix determines identifies a target object for the operation, which is
either a task (for an entry call) or a protected object (for an entry call or a protected subprogram call). The target object is considered an implicit parameter to the operation, and is determined by the operation name (or prefix) used in the call on the operation, as follows:

To be honest: \{AI05-0291-1\} This wording uses "denotes" to mean "denotes a view of an entity" (when the term is used in Legality Rules), and "denotes an entity" (when the term is used in Dynamic Semantics rules). It does not mean "view of a declaration", as that would not include renames (a renames is not an entry or protected subprogram).

- \{AI05-0291-1\} If it is a direct_name or expanded name that denotes the declaration (or body) of the operation, then the target object is implicitly specified to be the current instance of the task or protected unit immediately enclosing the operation; such a call using such a name is defined to be an internal call;

- \{AI05-0291-1\} If it is a selected_component that is not an expanded name, then the target object is explicitly specified to be the task or protected object denoted by the prefix of the name; such a call using such a name is defined to be an external call;

Discussion: For example:

```ada
protected type Pt is
  procedure Op1;
  procedure Op2;
end Pt;

PO : Pt;
Other_Object : Some_Other_Protected_Type;

protected body Pt is
  procedure Op1 is begin ... end Op1;

procedure Op2 is
  begin
    Op1; -- An internal call.
    Pt.Op1; -- Another internal call.
    PO.Op1; -- An external call. It the current instance is PO, then
    -- this is a bounded error (see 9.5.1).
    Other_Object.Some_Op; -- An external call.
  end Op2;
end Pt;
```

- \{AI05-0291-1\} If the name or prefix is a dereference (implicit or explicit) of an access-to-protected-subprogram value, then the target object is determined by the prefix of the Access attribute_reference that produced the access value originally; a-and the call using such a name is defined to be an external call;

- If the name or prefix denotes a subprogram_renaming_declaration, then the target object is as determined by the name of the renamed entity.

A corresponding definition of target object applies to a requeue_statement (see 9.5.4), with a corresponding distinction between an internal requeue and an external requeue.

Legality Rules

- \{AI95-00345-01\} \{AI05-0225-1\} \{AI05-0291-1\} If a name or prefix determines a target object, and the name denotes The view of the target protected object associated with a call of a protected entry/procedure or procedure, then the target objectentry shall be a variable, unless the prefix is for an attribute reference to the Count attribute (see 9.9).

Reason: \{AI05-0225-1\} The point is to prevent any calls to such a name whose target object is a constant view of a protected object, directly, or via an access value, renames, or generic formal subprogram. It is, however, legal to say P'Count in a protected function body, even though the protected object is a constant view there.
Ramification: \(\text{AI05-0291-1}\) This rule does not apply to calls that are not to a prefixed view. Specifically a "normal" call to a primitive operation of a limited interface is not covered by this rule. In that case, the normal parameter passing mode checks will prevent passing a constant protected object to an operation implemented by a protected entry or procedure as the mode is required to be \textbf{in out} or \textbf{out}.

**Dynamic Semantics**

Within the body of a protected operation, the current instance (see 8.6) of the immediately enclosing protected unit is determined by the target object specified (implicitly or explicitly) in the call (or requeue) on the protected operation.

To be honest: The current instance is defined in the same way within the body of a subprogram declared immediately within a protected_body.

Any call on a protected procedure or entry of a target protected object is defined to be an update to the object, as is a requeue on such an entry.

Reason: Read/write access to the components of a protected object is granted while inside the body of a protected procedure or entry. Also, any protected entry call can change the value of the Count attribute, which represents an update. Any protected procedure call can result in servicing the entries, which again might change the value of a Count attribute.

**Syntax**

\(\text{AI05-0030-2}\) \(\text{AI05-0215-1}\) \text{\texttt{synchronization_kind ::=}}

\text{By_Entry | By_Protected_Procedure | Optional}

**Static Semantics**

\(\text{AI05-0215-1}\) For the declaration of a primitive procedure of a synchronized tagged type the following language-defined representation aspect may be specified with an \texttt{aspect_specification} (see 13.1.1):

Synchronization

If specified, the aspect definition shall be a \texttt{synchronization_kind}.

\textbf{Aspect Description for Synchronization:} Defines whether a given primitive operation of a synchronized interface must be implemented by an entry or protected procedure.

\(\text{AI05-0030-2}\) \(\text{AI05-0215-1}\) Inherited subprograms inherit the Synchronization aspect, if any, from the corresponding subprogram of the parent or progenitor type. If an overriding operation does not have a directly specified Synchronization aspect then the Synchronization aspect of the inherited operation is inherited by the overriding operation.

**Legality Rules**

\(\text{AI05-0030-2}\) \(\text{AI05-0215-1}\) The \texttt{synchronization_kind By_Protected_Procedure} shall not be applied to a primitive procedure of a task interface.

\(\text{AI05-0030-2}\) \(\text{AI05-0215-1}\) A procedure for which the specified \texttt{synchronization_kind} is \texttt{By_Entry} shall be implemented by an entry. A procedure for which the specified \texttt{synchronization_kind} is \texttt{By_Protected_Procedure} shall be implemented by a protected procedure. A procedure for which the specified \texttt{synchronization_kind} is \texttt{Optional} may be implemented by an entry or by a procedure (including a protected procedure).

\(\text{AI05-0030-2}\) \(\text{AI05-0215-1}\) If a primitive procedure overrides an inherited operation for which the Synchronization aspect has been specified to be \texttt{By_Entry} or \texttt{By_Protected_Procedure}, then any specification of the aspect Synchronization applied to the overriding operation shall have the same \texttt{synchronization_kind}.

\(\text{AI05-0030-2}\) In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit.
9.5.1 Protected Subprograms and Protected Actions

A protected subprogram is a subprogram declared immediately within a protected definition. Protected procedures provide exclusive read-write access to the data of a protected object; protected functions provide concurrent read-only access to the data.

Ramification: A subprogram declared immediately within a protected body is not a protected subprogram; it is an intrinsic subprogram. See 6.3.1, “Conformance Rules”.

Static Semantics

[Within the body of a protected function (or a function declared immediately within a protected body), the current instance of the enclosing protected unit is defined to be a constant (that is, its subcomponents may be read but not updated). Within the body of a protected procedure (or a procedure declared immediately within a protected body), and within an entry body, the current instance is defined to be a variable (updating is permitted).]

Proof: All constant views are defined in 3.3, “Objects and Named Numbers”; anything not named there is a variable view.

Ramification: The current instance is like an implicit parameter, of mode in for a protected function, and of mode in out for a protected procedure (or protected entry).

Dynamic Semantics

For the execution of a call on a protected subprogram, the evaluation of the name or prefix and of the parameter associations, and any assigning back of in out or out parameters, proceeds as for a normal subprogram call (see 6.4). If the call is an internal call (see 9.5), the body of the subprogram is executed as for a normal subprogram call. If the call is an external call, then the body of the subprogram is executed as part of a new protected action on the target protected object; the protected action completes after the body of the subprogram is executed. [A protected action can also be started by an entry call (see 9.5.3).]

A new protected action is not started on a protected object while another protected action on the same protected object is underway, unless both actions are the result of a call on a protected function. This rule is expressible in terms of the execution resource associated with the protected object:

- Starting a protected action on a protected object corresponds to acquiring the execution resource associated with the protected object, either for concurrent read-only access if the protected action is for a call on a protected function, or for exclusive read-write access otherwise;
• Completing the protected action corresponds to releasing the associated execution resource.

[After performing an operation on a protected object other than a call on a protected function, but prior to completing the associated protected action, the entry queues (if any) of the protected object are serviced (see 9.5.3).]

Bounded (Run-Time) Errors

During a protected action, it is a bounded error to invoke an operation that is potentially blocking. The following are defined to be potentially blocking operations:

Reason: Some of these operations are not directly blocking. However, they are still treated as bounded errors during a protected action, because allowing them might impose an undesirable implementation burden.

• a select_statement;
• an accept_statement;
• an entry_call_statement;
• a delay_statement;
• an abort_statement;
• task creation or activation;
• an external call on a protected subprogram (or an external requeue) with the same target object as that of the protected action;

Reason: This is really a deadlocking call, rather than a blocking call, but we include it in this list for simplicity.

• a call on a subprogram whose body contains a potentially blocking operation.

Reason: This allows an implementation to check and raise Program_Error as soon as a subprogram is called, rather than waiting to find out whether it actually reaches the potentially blocking operation. This in turn allows the potentially blocking operation check to be performed prior to run time in some environments.

If the bounded error is detected, Program_Error is raised. If not detected, the bounded error might result in deadlock or a (nested) protected action on the same target object.

Discussion: [AI95-00305-01] By “nested protected action”, we mean that an additional protected action can be started by another task on the same protected object. This means that mutual exclusion may be broken in this bounded error case. A way to ensure that this does not happen is to use pragma Detect_Blocking (see H.5).

Certain language-defined subprograms are potentially blocking. In particular, the subprograms of the language-defined input-output packages that manipulate files (implicitly or explicitly) are potentially blocking. Other potentially blocking subprograms are identified where they are defined. When not specified as potentially blocking, a language-defined subprogram is nonblocking.

Discussion: [AI95-00178-01] Any subprogram in a language-defined input-output package that has a file parameter or result or operates on a default file is considered to manipulate a file. An instance of a language-defined input-output generic package provides subprograms that are covered by this rule. The only subprograms in language-defined input-output packages not covered by this rule (and thus not potentially blocking) are the Get and Put routines that take string parameters defined in the packages nested in Text_IO.

NOTES

19 If two tasks both try to start a protected action on a protected object, and at most one is calling a protected function, then only one of the tasks can proceed. Although the other task cannot proceed, it is not considered blocked, and it might be consuming processing resources while it awaits its turn. There is no language-defined ordering or queuing presumed for tasks competing to start a protected action — on a multiprocessor such tasks might use busy-waiting; for monoprocessor considerations, see D.3, “Priority Ceiling Locking”.

Discussion: The intended implementation on a multi-processor is in terms of “spin locks” — the waiting task will spin.

20 The body of a protected unit may contain declarations and bodies for local subprograms. These are not visible outside the protected unit.
The body of a protected function can contain internal calls on other protected functions, but not protected procedures, because the current instance is a constant. On the other hand, the body of a protected procedure can contain internal calls on both protected functions and procedures.

From within a protected action, an internal call on a protected subprogram, or an external call on a protected subprogram with a different target object is not considered a potentially blocking operation.

**Reason:** This is because a task is not considered blocked while attempting to acquire the execution resource associated with a protected object. The acquisition of such a resource is rather considered part of the normal competition for execution resources between the various tasks that are ready. External calls that turn out to be on the same target object are considered potentially blocking, since they can deadlock the task indefinitely.

The *pragma* Detect Blocking may be used to ensure that all executions of potentially blocking operations during a protected action raise Program_Error. See H.5.

**Examples**

Examples of protected subprogram calls (see 9.4):

```ada
Shared_Array.Set_Component(N, E);
E := Shared_Array.Component(M);
Control.Release;
```

**Wording Changes from Ada 95**

Added a note pointing out the existence of *pragma* Detect Blocking. This pragma can be used to ensure portable (somewhat pessimistic) behavior of protected actions by converting the Bounded Error into a required check.

### 9.5.2 Entries and Accept Statements

Entry declarations, with the corresponding entry bodies or accept statements, are used to define potentially queued operations on tasks and protected objects.

**Syntax**

```ada
entry_declaration ::= 
  [overriding_indicator] 
  entry defining_identifier [(discrete_subtype_definition)] parameter_profile 
                           [aspect_specification];
accept_statement ::= 
  accept entry direct_name [(entry_index)] parameter_profile [do 
                            handled_sequence_of_statements end [entry_identifier]];
```

**Reason:** We cannot use defining_identifier for accept statements. Although an accept_statement is sort of like a body, it can appear nested within a block_statement, and therefore be hidden from its own entry by an outer homograph.

**Discussion:** [AI95-00397-01] We don't allow an overriding_indicator on an entry_body because entries always implement procedures at the point of the type declaration, there is no late implementation. And we don't want to have to think about overriding_indicators on accept_statements.
entry_index_specification ::= for defining_identifier in discrete_subtype_definition

If an entry_identifier appears at the end of an accept_statement, it shall repeat the entry_direct_name. If an entry_identifier appears at the end of an entry_body, it shall repeat the defining_identifier.

[An entry_declaration is allowed only in a protected or task declaration.]

Proof: This follows from the BNF.

\{AI95-00397-01\} An overriding_indicator is not allowed in an entry_declaration that includes a discrete_subtype_definition.

Reason: An entry family can never implement something, so allowing an indicator is felt by the majority of the ARG to be redundant.

Name Resolution Rules

In an accept_statement, the expected profile for the entry_direct_name is that of the entry_declaration; the expected type for an entry_index is that of the subtype defined by the discrete_subtype_definition of the corresponding entry_declaration.

Within the handled_sequence_of_statements of an accept_statement, if a selected_component has a prefix that denotes the corresponding entry_declaration, then the entity denoted by the prefix is the accept_statement, and the selected_component is interpreted as an expanded name (see 4.1.3)[; the selector_name of the selected_component has to be the identifier for some formal parameter of the accept_statement].

Proof: The only declarations that occur immediately within the declarative region of an accept_statement are those for its formal parameters.

Legality Rules

An entry_declaration in a task declaration shall not contain a specification for an access parameter (see 3.10).

Reason: Access parameters for task entries would require a complex implementation. For example:

```ada
task T is
  entry E(Z : access Integer); -- Illegal!
end T;
task body T is
begin
  declare
    type A is access all Integer;
    X : A;
    Int : aliased Integer;
task Inner;
task body Inner is
begin
  T.E(Int'Access);
end Inner;
begi
  accept E(Z : access Integer) do
    X := A(Z); -- Accessibility_Check
  end E;
end;  
end T;
```

Implementing the Accessibility_Check inside the accept_statement for E is difficult, since one does not know whether the entry caller is calling from inside the immediately enclosing declare block or from outside it. This means that the lexical nesting level associated with the designated object is not sufficient to determine whether the Accessibility_Check should pass or fail.

Note that such problems do not arise with protected entries, because entry_bodies are always nested immediately within the protected_body; they cannot be further nested as can accept_statements, nor can they be called from within the protected_body (since no entry calls are permitted inside a protected_body).
If an entry declaration has an overriding indicator, then at the point of the declaration:

- if the overriding indicator is overriding, then the entry shall implement an inherited subprogram;
- if the overriding indicator is not overriding, then the entry shall not implement any inherited subprogram.

In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit.

Discussion: These rules are subtly different than those for subprograms (see 8.3.1) because there cannot be “late” inheritance of primitives from interfaces. Hidden (that is, private) interfaces are prohibited explicitly (see 7.3), as are hidden primitive operations (as private operations of public abstract types are prohibited — see 3.9.3).

For an accept_statement, the innermost enclosing body shall be a task_body, and the entry_direct_name shall denote an entry_declaration in the corresponding task declaration; the profile of the accept_statement shall conform fully to that of the corresponding entry_declaration. An accept_statement shall have a parenthesized entry_index if and only if the corresponding entry_declaration has a discrete_subtype_definition.

An accept_statement shall not be within another accept_statement that corresponds to the same entry_declaration, nor within an asynchronous_select inner to the enclosing task_body.

Reason: Accept_statements are required to be immediately within the enclosing task_body (as opposed to being in a nested subprogram) to ensure that a nested task does not attempt to accept the entry of its enclosing task. We considered relaxing this restriction, either by making the check a run-time check, or by allowing a nested task to accept an entry of its enclosing task. However, neither change seemed to provide sufficient benefit to justify the additional implementation burden.

Nested accept_statements for the same entry (or entry family) are prohibited to ensure that there is no ambiguity in the resolution of an expanded name for a formal parameter of the entry. This could be relaxed by allowing the inner one to hide the outer one from all visibility, but again the small added benefit didn't seem to justify making the change for Ada 95.

Accept_statements are not permitted within asynchronous_select statements to simplify the semantics and implementation: an accept_statement in an abortable_part could result in Tasking_Error being propagated from an entry call even though the target task was still callable; implementations that use multiple tasks implicitly to implement an asynchronous_select might have trouble supporting "up-level" accepts. Furthermore, if accept_statements were permitted in the abortable_part, a task could call its own entry and then accept it in the abortable_part, leading to rather unusual and possibly difficult-to-specify semantics.

An entry_declaration of a protected unit requires a completion[, which shall be an entry_body,] and every entry_body shall be the completion of an entry_declaration of a protected unit. The profile of the entry_body shall conform fully to that of the corresponding declaration.

Ramification: An entry_declaration, unlike a subprogram_declaration, cannot be completed with a renaming_declaration.

To be honest: {AI05-0229-1} If (the completion can be a pragma Import, if the implementation supports it _the entry body can be imported (using aspect Import, see B.1), in which case no explicit entry_body is allowed.

Discussion: The above applies only to protected entries, which are the only ones completed with entry_bodies. Task entries have corresponding accept_statements instead of having entry_bodies, and we do not consider an accept_statement to be a “completion,” because a task entry_declaration is allowed to have zero, one, or more than one corresponding accept_statements.

An entry_body_formal_part shall have an entry_index_specification if and only if the corresponding entry_declaration has a discrete_subtype_definition. In this case, the discrete_subtype_definitions of the entry_declaration and the entry_index_specification shall fully conform to one another (see 6.3.1).

A name that denotes a formal parameter of an entry_body is not allowed within the entry_barrier of the entry_body.
Static Semantics

The parameter modes defined for parameters in the parameter_profile of an entry_declaration are the same as for a subprogram_declaration and have the same meaning (see 6.2).

Discussion: Note that access parameters are not allowed for task entries (see above). An entry_declaration with a discrete_subtype_definition (see 3.6) declares a family of distinct entries having the same profile, with one such entry for each value of the entry index subtype defined by the discrete_subtype_definition. [A name for an entry of a family takes the form of an indexed_component, where the prefix denotes the entry_declaration for the family, and the index value identifies the entry within the family.] The term single entry is used to refer to any entry other than an entry of an entry family.

In the entry_body for an entry family, the entry_index_specification declares a named constant whose subtype is the entry index subtype defined by the corresponding entry_declaration; the value of the named entry index identifies which entry of the family was called.

Ramification: The discrete_subtype_definition of the entry_index_specification is not elaborated; the subtype of the named constant declared is defined by the discrete_subtype_definition of the corresponding entry_declaration, which is elaborated, either when the type is declared, or when the object is created, if its constraint is per-object.

Dynamic Semantics

The elaboration of an entry_declaration for an entry family consists of the elaboration of the discrete_subtype_definition, as described in 3.8. For the elaboration of an entry_declaration for an entry family, if the discrete_subtype_definition contains no per-object expressions (see 3.8), then the discrete_subtype_definition is elaborated. Otherwise, the elaboration of the entry_declaration consists of the evaluation of any expression of the discrete_subtype_definition that is not a per-object expression (or part of one). The elaboration of an entry_declaration for a single entry has no effect.

Discussion: The elaboration of the declaration of a protected subprogram has no effect, as specified in subclause 6.1. The default initialization of an object of a task or protected type is covered in 3.3.1.

[The actions to be performed when an entry is called are specified by the corresponding accept_statements (if any) for an entry of a task unit, and by the corresponding entry_body for an entry of a protected unit.]

For the execution of an accept_statement, the entry_index, if any, is first evaluated and converted to the entry index subtype; this index value identifies which entry of the family is to be accepted. Further execution of the accept_statement is then blocked until a caller of the corresponding entry is selected (see 9.5.3), whereupon the handled_sequence_of_statements, if any, of the accept_statement is executed, with the formal parameters associated with the corresponding actual parameters of the selected entry call. Upon completion of the handled_sequence_of_statements, the accept_statement completes and is left. When an exception is propagated from the handled_sequence_of_statements of an accept_statement, the same exception is also raised by the execution of the corresponding entry_call_statement.

Ramification: This is in addition to propagating it to the construct containing the accept_statement. In other words, for a rendezvous, the raising splits in two, and continues concurrently in both tasks.

The caller gets a new occurrence; this isn't considered propagation.

Note that we say “propagated from the handled_sequence_of_statements of an accept_statement”, not “propagated from an accept_statement.” The latter would be wrong — we don't want exceptions propagated by the entry_index to be sent to the caller (there is none yet!).

The above interaction between a calling task and an accepting task is called a rendezvous. [After a rendezvous, the two tasks continue their execution independently.]
An entry_body is executed when the condition of the entry_barrier evaluates to True and a caller of the corresponding single entry, or entry of the corresponding entry family, has been selected (see 9.5.3). For the execution of the entry_body, the declarative_part of the entry_body is elaborated, and the handled_sequence_of_statements of the body is executed, as for the execution of a subprogram_body. The value of the named entry index, if any, is determined by the value of the entry index specified in the entry_name of the selected entry call (or intermediate requeue_statement — see 9.5.4).

To be honest: If the entry had been renamed as a subprogram, and the call was a procedure_call_statement using the name declared by the renaming, the entry index (if any) comes from the entry name specified in the subprogram_renaming_declaration.

NOTES

24 A task entry has corresponding accept_statements (zero or more), whereas a protected entry has a corresponding entry_body (exactly one).

25 A consequence of the rule regarding the allowed placements of accept_statements is that a task can execute accept_statements only for its own entries.

26 A return_statement (see 6.5) or a requeue_statement (see 9.5.4) may be used to complete the execution of an accept_statement or an entry_body.

Ramification: An accept_statement need not have a handled_sequence_of_statements even if the corresponding entry has parameters. Equally, it can have a handled_sequence_of_statements even if the corresponding entry has no parameters.

Ramification: A single entry overloads a subprogram, an enumeration literal, or another single entry if they have the same defining_identifier. Overloading is not allowed for entry family names. A single entry or an entry of an entry family can be renamed as a procedure as explained in 8.5.4.

27 The condition in the entry_barrier may reference anything visible except the formal parameters of the entry. This includes the entry index (if any), the components (including discriminants) of the protected object, the Count attribute of an entry of that protected object, and data global to the protected unit.

28 The restriction against referencing the formal parameters within an entry_barrier ensures that all calls of the same entry see the same barrier value. If it is necessary to look at the parameters of an entry call before deciding whether to handle it, the entry_barrier can be “when True” and the caller can be requeued (on some private entry) when its parameters indicate that it cannot be handled immediately.

Examples of entry declarations:

```ada
entry Read(V : out Item);
entry Seize;
entry Request(Level)(D : Item);  -- a family of entries
```

Examples of accept statements:

```ada
accept Shut_Down;
accept Read(V : out Item) do
   V := Local_Item;
end Read;
accept Request(Low)(D : Item) do
   ...
end Request;
```

Extensions to Ada 83

The syntax rule for entry_body is new.

Accept_statements can now have exception_handlers.

Wording Changes from Ada 95

37.a Corrigendum: Clarified the elaboration of per-object constraints.

37.b Overriding_indicators can be used on entries; this is only useful when a task or protected type inherits from an interface.
9.5.3 Entry Calls

[An entry_call_statement (an entry call) can appear in various contexts.] A simple entry call is a stand-alone statement that represents an unconditional call on an entry of a target task or a protected object. [Entry calls can also appear as part of select_statements (see 9.7).]

Syntax

entry_call_statement ::= entry_name [actual_parameter_part];

Name Resolution Rules

The entry_name given in an entry_call_statement shall resolve to denote an entry. The rules for parameter associations are the same as for subprogram calls (see 6.4 and 6.4.1).

Static Semantics

[The entry_name of an entry_call_statement specifies (explicitly or implicitly) the target object of the call, the entry or entry family, and the entry index, if any (see 9.5).]

Dynamic Semantics

Under certain circumstances (detailed below), an entry of a task or protected object is checked to see whether it is open or closed:

- \{AI05-0264-1\} An entry of a task is open if the task is blocked on an accept_statement that corresponds to the entry (see 9.5.2), or on a selective_accept (see 9.7.1) with an open accept_alternative that corresponds to the entry; otherwise it is closed.
- \{AI05-0264-1\} An entry of a protected object is open if the condition of the entry_barrier of the corresponding entry_body evaluates to True; otherwise it is closed. If the evaluation of the condition propagates an exception, the exception Program_Error is propagated to all current callers of all entries of the protected object.

**Reason:** An exception during barrier evaluation is considered essentially a fatal error. All current entry callers are notified with a Program_Error. In a fault-tolerant system, a protected object might provide a Reset protected procedure, or equivalent, to support attempts to restore such a "broken" protected object to a reasonable state.

**Discussion:** Note that the definition of when a task entry is open is based on the state of the (accepting) task, whereas the "openness" of a protected entry is defined only when it is explicitly checked, since the barrier expression needs to be evaluated. Implementation permissions are given (below) to allow implementations to evaluate the barrier expression more or less often than it is checked, but the basic semantic model presumes it is evaluated at the times when it is checked.

For the execution of an entry_call_statement, evaluation of the name and of the parameter associations is as for a subprogram call (see 6.4). The entry call is then issued: For a call on an entry of a protected object, a new protected action is started on the object (see 9.5.1). The named entry is checked to see if it is open; if open, the entry call is said to be selected immediately, and the execution of the call proceeds as follows:

- For a call on an open entry of a task, the accepting task becomes ready and continues the execution of the corresponding accept_statement (see 9.5.2).
- For a call on an open entry of a protected object, the corresponding entry_body is executed (see 9.5.2) as part of the protected action.

If the accept_statement or entry_body completes other than by a requeue (see 9.5.4), return is made to the caller (after servicing the entry queues — see below); any necessary assigning back of formal to
actual parameters occurs, as for a subprogram call (see 6.4.1); such assignments take place outside of any protected action.

**Ramification:** The return to the caller will generally not occur until the protected action completes, unless some other thread of control is given the job of completing the protected action and releasing the associated execution resource.

If the named entry is closed, the entry call is added to an *entry queue* (as part of the protected action, for a call on a protected entry), and the call remains queued until it is selected or cancelled; there is a separate (logical) entry queue for each entry of a given task or protected object [(including each entry of an entry family)].

When a queued call is *selected*, it is removed from its entry queue. Selecting a queued call from a particular entry queue is called *servicing* the entry queue. An entry with queued calls can be serviced under the following circumstances:

- When the associated task reaches a corresponding *accept_statement*, or a *selective_accept* with a corresponding open *accept_alternative*;
- If after performing, as part of a protected action on the associated protected object, an operation on the object other than a call on a protected function, the entry is checked and found to be open.

If there is at least one call on a queue corresponding to an open entry, then one such call is selected according to the *entry queuing policy* in effect (see below), and the corresponding *accept_statement* or *entry_body* is executed as above for an entry call that is selected immediately.

The entry queuing policy controls selection among queued calls both for task and protected entry queues. The default entry queuing policy is to select calls on a given entry queue in order of arrival. If calls from two or more queues are simultaneously eligible for selection, the default entry queuing policy does not specify which queue is serviced first. Other entry queuing policies can be specified by *pragma*s (see D.4).

For a protected object, the above servicing of entry queues continues until there are no open entries with queued calls, at which point the protected action completes.

**Discussion:** While servicing the entry queues of a protected object, no new calls can be added to any entry queue of the object, except due to an internal requeue (see 9.5.4). This is because the first step of a call on a protected entry is to start a new protected action, which implies acquiring (for exclusive read-write access) the execution resource associated with the protected object, which cannot be done while another protected action is already in progress.

For an entry call that is added to a queue, and that is not the *triggering_statement* of an asynchronous_*-select* (see 9.7.4), the calling task is blocked until the call is cancelled, or the call is selected and a corresponding *accept_statement* or *entry_body* completes without requeuing. In addition, the calling task is blocked during a rendezvous.

**Ramification:** For a call on a protected entry, the caller is not blocked if the call is selected immediately, unless a requeue causes the call to be queued.

An attempt can be made to cancel an entry call upon an abort (see 9.8) and as part of certain forms of *select_statement* (see 9.7.2, 9.7.3, and 9.7.4). The cancellation does not take place until a point (if any) when the call is on some entry queue, and not protected from cancellation as part of a requeue (see 9.5.4); at such a point, the call is removed from the entry queue and the call completes due to the cancellation. The cancellation of a call on an entry of a protected object is a protected action[ and as such cannot take place while any other protected action is occurring on the protected object. Like any protected action, it includes servicing of the entry queues (in case some entry barrier depends on a Count attribute).]

**Implementation Note:** [AI95-00114-01] In the case of an attempted cancellation due to abort, this removal might have to be performed by the calling task itself if the ceiling priority of the protected object is lower than the priority of the task initiating the abort.

A call on an entry of a task that has already completed its execution raises the exception Tasking_Error at the point of the call; similarly, this exception is raised at the point of the call if the called task completes.
its execution or becomes abnormal before accepting the call or completing the rendezvous (see 9.8). This applies equally to a simple entry call and to an entry call as part of a select_statement.

Implementation Permissions

An implementation may perform the sequence of steps of a protected action using any thread of control; it need not be that of the task that started the protected action. If an entry_body completes without requeuing, then the corresponding calling task may be made ready without waiting for the entire protected action to complete.

Reason: These permissions are intended to allow flexibility for implementations on multiprocessors. On a monoprocessor, which thread of control executes the protected action is essentially invisible, since the thread is not abortable in any case, and the "current_task" function is not guaranteed to work during a protected action (see C.7.1.C.2).

When the entry of a protected object is checked to see whether it is open, the implementation need not reevaluate the condition of the corresponding entry_barrier if no variable or attribute referenced by the condition (directly or indirectly) has been altered by the execution (or cancellation) of a protected procedure or entry call on the object since the condition was last evaluated.

Ramification: Changes to variables referenced by an entry barrier that result from actions outside of a protected procedure or entry call on the protected object need not be "noticed." For example, if a global variable is referenced by an entry barrier, it should not be altered (except as part of a protected action on the object) any time after the barrier is first evaluated. In other words, globals can be used to "parameterize" a protected object, but they cannot reliably be used to control it after the first use of the protected object.

Implementation Note: Note that even if a global variable is volatile, the implementation need only reevaluate a barrier if the global is updated during a protected action on the protected object. This ensures that an entry-open bit-vector implementation approach is possible, where the bit-vector is computed at the end of a protected action, rather than upon each entry call.

An implementation may evaluate the conditions of all entry_barriers of a given protected object any time any entry of the object is checked to see if it is open.

Ramification: In other words, any side effects of evaluating an entry barrier should be innocuous, since an entry barrier might be evaluated more or less often than is implied by the "official" dynamic semantics.

Implementation Note: It is anticipated that when the number of entries is known to be small, all barriers will be evaluated any time one of them needs to be, to produce an "entry-open bit-vector." The appropriate bit will be tested when the entry is called, and only if the bit is false will a check be made to see whether the bit-vector might need to be recomputed. This should allow an implementation to maximize the performance of a call on an open entry, which seems like the most important case.

In addition to the entry-open bit-vector, an "is-valid" bit is needed per object, which indicates whether the current bit-vector setting is valid. A "depends-on-Count-attribute" bit is needed per type. The "is-valid" bit is set to false (as are all the bits of the bit-vector) when the protected object is first created, as well as any time an exception is propagated from computing the bit-vector. Is-valid would also be set false any time the Count is changed and "depends-on-Count-attribute" is true for the type, or a protected procedure or entry returns indicating it might have updated a variable referenced in some barrier.

A single procedure can be compiled to evaluate all of the barriers, set the entry-open bit-vector accordingly, and set the is-valid bit to true. It could have a "when others" handler to set them all false, and call a routine to propagate Program_Error to all queued callers.

For protected types where the number of entries is not known to be small, it makes more sense to evaluate a barrier only when the corresponding entry is checked to see if it is open. It isn't worth saving the state of the entry between checks, because of the space that would be required. Furthermore, the entry queues probably want to take up space only when there is actually a caller on them, so rather than an array of all entry queues, a linked list of nonempty entry queues make the most sense in this case, with the first caller on each entry queue acting as the queue header.

When an attempt is made to cancel an entry call, the implementation need not make the attempt using the thread of control of the task (or interrupt) that initiated the cancellation; in particular, it may use the thread of control of the caller itself to attempt the cancellation, even if this might allow the entry call to be selected in the interim.
Reason: Because cancellation of a protected entry call is a protected action (which helps make the Count attribute of a protected entry meaningful), it might not be practical to attempt the cancellation from the thread of control that initiated the cancellation. For example, if the cancellation is due to the expiration of a delay, it is unlikely that the handler of the timer interrupt could perform the necessary protected action itself (due to being on the interrupt level). Similarly, if the cancellation is due to an abort, it is possible that the task initiating the abort has a priority higher than the ceiling priority of the protected object (for implementations that support ceiling priorities). Similar considerations could apply in a multiprocessor situation.

NOTES

28 If an exception is raised during the execution of an entry_body, it is propagated to the corresponding caller (see 11.4).
29 For a call on a protected entry, the entry is checked to see if it is open prior to queuing the call, and again thereafter if its Count attribute (see 9.9) is referenced in some entry barrier.

Ramification: Given this, extra care is required if a reference to the Count attribute of an entry appears in the entry's own barrier.

Reason: An entry is checked to see if it is open prior to queuing to maximize the performance of a call on an open entry.

30 In addition to simple entry calls, the language permits timed, conditional, and asynchronous entry calls (see 9.7.2, 9.7.3, and see 9.7.4).

Ramification: A task can call its own entries, but the task will deadlock if the call is a simple entry call.

31 The condition of an entry_barrier is allowed to be evaluated by an implementation more often than strictly necessary, even if the evaluation might have side effects. On the other hand, an implementation need not reevaluate the condition if nothing it references was updated by an intervening protected action on the protected object, even if the condition references some global variable that might have been updated by an action performed from outside of a protected action.

Examples

Examples of entry calls:

Agent.Shut_Down;                      -- see 9.1
Parser.Next_Lexeme(E);                -- see 9.1
Pool(5).Read(Next_Char);              -- see 9.1
Controller.Request(Low)(Some_Item);   -- see 9.1
Flags(3).Seize;                       -- see 9.4

9.5.4 Requeue Statements

[A requeue_statement can be used to complete an accept_statement or entry_body, while redirecting the corresponding entry call to a new (or the same) entry queue. Such a requeue can be performed with or without allowing an intermediate cancellation of the call, due to an abort or the expiration of a delay. ]

Syntax

requeue_statement ::= requeue procedure_or_entry_entry_name [with abort];

Name Resolution Rules

The procedure_or_entry_entry_name of a requeue_statement shall resolve to denote a procedure or an entry (the requeue target entry). The profile of the entry, or the profile or prefixed profile of the procedure, shall either have has no parameters, or have that has a profile that is type conformant (see 6.3.1) with the profile of the innermost enclosing entry_body or accept_statement.

Legality Rules

A requeue_statement shall be within a callable construct that is either an entry_body or an accept_statement, and this construct shall be the innermost enclosing body or callable construct.

If the requeue target entry has parameters, then its (prefixed) profile shall be subtype conformant with the profile of the innermost enclosing callable construct.
If the target is a procedure, the name shall denote a renaming of an entry, or shall denote a view or a prefixed view of a primitive subprogram of a synchronized interface, where the first parameter of the unprefixed view of the primitive subprogram shall be a controlling parameter, and the Synchronization aspect shall be specified with synchronization_kind By_Entry for the primitive subprogram.

In a requeue_statement of an accept_statement of some task unit, either the target object shall be a part of a formal parameter of the accept_statement, or the accessibility level of the target object shall not be equal to or statically deeper than any enclosing accept_statement of the task unit. In a requeue_statement of an entry_body of some protected unit, either the target object shall be a part of a formal parameter of the entry_body, or the accessibility level of the target object shall not be statically deeper than that of the entry_declaration for the entry_body.

**Ramification:** In the entry_body case, the intent is that the target object can be global, or can be a component of the protected unit, but cannot be a local variable of the entry_body.

**Reason:** These restrictions ensure that the target object of the requeue outlives the completion and finalization of the enclosing callable construct. They also prevent requeuing from a nested accept_statement on a parameter of an outer accept_statement, which could create some strange "long-distance" connections between an entry caller and its server.

Note that in the strange case where a task_body is nested inside an accept_statement, it is permissible to requeue from an accept_statement of the inner task_body on parameters of the outer accept_statement. This is not a problem because all calls on the inner task have to complete before returning from the outer accept_statement, meaning no "dangling calls" will be created.

**Implementation Note:** By disallowing certain requeues, we ensure that the normal terminate_alternative rules remain sensible, and that explicit clearing of the entry queues of a protected object during finalization is rarely necessary. In particular, such clearing of the entry queues is necessary only (ignoring premature Unchecked_Deallocation) for protected objects declared in a task_body (or created by an allocator for an access type declared in such a body) containing one or more requeue_statements. Protected objects declared in subprograms, or at the library level, will never need to have their entry queues explicitly cleared during finalization.

**Dynamic Semantics**

The execution of a requeue_statement proceeds by first evaluating the procedure_or_entry_name[, including the prefix identifying the target task or protected object and the expression identifying the entry within an entry family, if any]. The entry_body or accept_statement enclosing the requeue_statement is then completed[, finalized, and left (see 7.6.1)].

For the execution of a requeue on an entry of a target task, after leaving the enclosing callable construct, the named entry is checked to see if it is open and the requeued call is either selected immediately or queued, as for a normal entry call (see 9.5.3).

For the execution of a requeue on an entry of a target protected object, after leaving the enclosing callable construct:

- if the requeue is an internal requeue (that is, the requeue is back on an entry of the same protected object — see 9.5), the call is added to the queue of the named entry and the ongoing protected action continues (see 9.5.1);

  **Ramification:** Note that for an internal requeue, the call is queued without checking whether the target entry is open. This is because the entry queues will be serviced before the current protected action completes anyway, and considering the requeued call immediately might allow it to "jump" ahead of existing callers on the same queue.

- if the requeue is an external requeue (that is, the target protected object is not implicitly the same as the current object — see 9.5), a protected action is started on the target object and proceeds as for a normal entry call (see 9.5.3).

If the requeue target new_entry named in the requeue_statement has formal parameters, then during the execution of the accept_statement or entry_body corresponding to the new entry, the formal parameters denote the same objects as did the corresponding formal parameters of the callable
construct completed by the requeue. [In any case, no parameters are specified in a requeue_statement; any parameter passing is implicit.]

If the requeue_statement includes the reserved words with abort (it is a requeue-with-abort), then:

- if the original entry call has been aborted (see 9.8), then the requeue acts as an abort completion point for the call, and the call is cancelled and no requeue is performed;
- if the original entry call was timed (or conditional), then the original expiration time is the expiration time for the requeued call.

If the reserved words with abort do not appear, then the call remains protected against cancellation while queued as the result of the requeue_statement.

**Ramification:** This protection against cancellation lasts only until the call completes or a subsequent requeue-with-abort is performed on the call.

**Reason:** We chose to protect a requeue, by default, against abort or cancellation. This seemed safer, since it is likely that extra steps need to be taken to allow for possible cancellation once the servicing of an entry call has begun. This also means that in the absence of with abort the usual Ada 83 behavior is preserved, namely that once an entry call is accepted, it cannot be cancelled until it completes.

**NOTES**
32 A requeue is permitted from a single entry to an entry of an entry family, or vice-versa. The entry index, if any, plays no part in the subtype conformance check between the profiles of the two entries; an entry index is part of the entry_name for an entry of a family.

**Examples**

Examples of requeue statements:

```
requeue Request(Medium) with abort;
  -- requeue on a member of an entry family of the current task, see 9.1
requeue Flags(I).Seize;
  -- requeue on an entry of an array component, see 9.4
```

**Extensions to Ada 83**

**Extensions to Ada 2005**

\{AI05-0030-2\} \{AI05-0215-1\} Added the ability to requeue on operations of synchronized interfaces that are declared to be an entry.

### 9.6 Delay Statements, Duration, and Time

[A delay_statement is used to block further execution until a specified expiration time is reached. The expiration time can be specified either as a particular point in time (in a delay_until_statement), or in seconds from the current time (in a delay_relative_statement). The language-defined package Calendar provides definitions for a type Time and associated operations, including a function Clock that returns the current time.]

**Syntax**

```
delay_statement ::= delay_until_statement | delay_relative_statement

delay_until_statement ::= delay until delay_expression;

delay_relative_statement ::= delay delay_expression;
```

**Name Resolution Rules**

The expected type for the delay_expression in a delay_relative_statement is the predefined type Duration. The delay_expression in a delay_until_statement is expected to be of any nonlimited type.
Legality Rules

\{AI05-0092-1\} There can be multiple time bases, each with a corresponding clock, and a corresponding time type. The type of the delay_expression in a delay_until_statement shall be a time type — either the type Time defined in the language-defined package Calendar (see below), the type Time in the package Real_Time (see D.8), or some other implementation-defined time type (see D.8).

**Implementation defined:** Any implementation-defined time types.

Static Semantics

[There is a predefined fixed point type named Duration, declared in the visible part of package Standard:] a value of type Duration is used to represent the length of an interval of time, expressed in seconds. [The type Duration is not specific to a particular time base, but can be used with any time base.]

\{AI05-0092-1\} A value of the type Time in package Calendar, or of some other implementation-defined time type, represents a time as reported by a corresponding clock.

The following language-defined library package exists:

```ada
package Ada.Calendar is
type Time is private;

{AI95-00351-01} subtype Year_Number is Integer range 1901 .. 23992099;
subtype Month_Number is Integer range 1 .. 12;
subtype Day_Number is Integer range 1 .. 31;
subtype Day_Duration is Duration range 0.0 .. 86_400.0;

Reason: A range of 500 years was chosen, as that only requires one extra bit for the year as compared to Ada 95. This was done to minimize disruptions with existing implementations. (One implementor reports that their time values represent nanoseconds, and this year range requires 63.77 bits to represent.)

function Clock return Time;
function Year (Date : Time) return Year_Number;
function Month (Date : Time) return Month_Number;
function Day (Date : Time) return Day_Number;
function Seconds (Date : Time) return Day_Duration;
procedure Split (Date  in Time;
    Year    : out Year_Number;
    Month   : out Month_Number;
    Day     : out Day_Number;
    Seconds : out Day_Duration);
function Time_Of (Year  : Year_Number;
    Month   : Month_Number;
    Day     : Day_Number;
    Seconds : Day_Duration := 0.0)
    return Time;
function "+" (Left : Time;   Right : Duration) return Time;
function "+" (Left : Duration; Right : Time) return Time;
function "-" (Left : Time;   Right : Duration) return Time;
function "-" (Left : Time;   Right : Time) return Duration;
function ">" (Left, Right : Time) return Boolean;
function ">="(Left, Right : Time) return Boolean;
function ">" (Left, Right : Time) return Boolean;
function ">="(Left, Right : Time) return Boolean;

Time_Error : exception;
private
    ... -- not specified by the language
end Ada.Calendar;
```
Dynamic Semantics

For the execution of a delay_statement, the delay_expression is first evaluated. For a delay_until_statement, the expiration time for the delay is the value of the delay_expression, in the time base associated with the type of the expression. For a delay_relative_statement, the expiration time is defined as the current time, in the time base associated with relative delays, plus the value of the delay_expression converted to the type Duration, and then rounded up to the next clock tick. The time base associated with relative delays is as defined in D.9, “Delay Accuracy” or is implementation defined.

Implementation defined: The time base associated with relative delays.

Ramification: Rounding up to the next clock tick means that the reading of the delay-relative clock when the delay expires should be no less than the current reading of the delay-relative clock plus the specified duration.

The task executing a delay_statement is blocked until the expiration time is reached, at which point it becomes ready again. If the expiration time has already passed, the task is not blocked.

Discussion: For a delay_relative_statement, this case corresponds to when the value of the delay_expression is zero or negative.

Even though the task is not blocked, it might be put back on the end of its ready queue. See D.2, “Priority Scheduling”.

{AI05-0092-1} If an attempt is made to cancel the delay_statement [(as part of an asynchronous_select or abort — see 9.7.4 and 9.8)], the statement is cancelled if the expiration time has not yet passed, thereby completing the delay_statement.

Reason: This is worded this way so that in an asynchronous_select where the triggering_statement is a delay_statement, an attempt to cancel the delay when the abortable_part completes is ignored if the expiration time has already passed, in which case the optional statements of the triggering_alternative are executed.

The time base associated with the type Time of package Calendar is implementation defined. The function Clock of package Calendar returns a value representing the current time for this time base. [The implementation-defined value of the named number System.Tick (see 13.7) is an approximation of the length of the real-time interval during which the value of Calendar.Clock remains constant.]

Implementation defined: The time base of the type Calendar.Time.

{AI95-00351-01} The functions Year, Month, Day, and Seconds return the corresponding values for a given value of the type Time, as appropriate to an implementation-defined time zone: the procedure Split returns all four corresponding values. Conversely, the function Time_Of combines a year number, a month number, a day number, and a duration, into a value of type Time. The operators "+" and "-" for addition and subtraction of times and durations, and the relational operators for times, have the conventional meaning.

Implementation defined: The time zone used for package Calendar operations.

Ramification: {AI05-0119-1} The behavior of these values and subprograms if the time zone changes is also implementation-defined. In particular, the changes associated with summer time adjustments (like Daylight Savings Time in the United States) should be treated as a change in the implementation-defined time zone. The language does not specify whether the time zone information is stored in values of type Time; therefore the results of binary operators are unspecified when the operands are the two values with different effective time zones. In particular, the results of "-" may differ from the "real" result by the difference in the time zone adjustment. Similarly, the result of UTC_TimeType_Offset (see 9.6.1) may or may not reflect a time zone adjustment.

If Time_Of is called with a seconds value of 86_400.0, the value returned is equal to the value of Time_Of for the next day with a seconds value of 0.0. The value returned by the function Seconds or through the Seconds parameter of the procedure Split is always less than 86_400.0.

{8652/0030} {AI95-00113-01} The exception Time_Error is raised by the function Time_Of if the actual parameters do not form a proper date. This exception is also raised by the operators "+" and "-" if the result is not representable in the type Time or Duration, as appropriate. This exception is also raised by the functions Year, Month, Day, and Seconds and the procedure Split if the year number of the given date is outside of the range of the subtype Year_Number.
To be honest: \{8652/0106\} \{AI95-00160-01\} By "proper date" above we mean that the given year has a month with the given day. For example, February 29th is a proper date only for a leap year. We do not mean to include the Seconds in this notion; in particular, we do not mean to require implementations to check for the “missing hour” that occurs when Daylight Savings Time starts in the spring.

Reason: \{8652/0030\} \{AI95-00113-01\} \{AI95-00351-01\} We allow Year and Split to raise Time_Error because the arithmetic operators are allowed (but not required) to produce times that are outside the range of years from 1901 to 2099. This is similar to the way integer operators may return values outside the base range of their type so long as the value is mathematically correct. We allow the functions Month, Day and Seconds to raise Time_Error so that they can be implemented in terms of Split.

Implementation Requirements

The implementation of the type Duration shall allow representation of time intervals (both positive and negative) up to at least 86400 seconds (one day); Duration'Small shall not be greater than twenty milliseconds. The implementation of the type Time shall allow representation of all dates with year numbers in the range of Year_Number[; it may allow representation of other dates as well (both earlier and later).]

Implementation Permissions

\{AI05-0092-1\} An implementation may define additional time types (see D.8).

An implementation may raise Time_Error if the value of a delay_expression in a delay_until_statement of a select_statement represents a time more than 90 days past the current time. The actual limit, if any, is implementation-defined.

Implementation defined: Any limit on delay_until_statements of select_statements.

Implementation Note: This allows an implementation to implement select_statement timeouts using a representation that does not support the full range of a time type. In particular 90 days of seconds can be represented in 23 bits, allowing a signed 24-bit representation for the seconds part of a timeout. There is no similar restriction allowed for stand-alone delay_until_statements, as these can be implemented internally using a loop if necessary to accommodate a long delay.

Implementation Advice

Whenever possible in an implementation, the value of Duration'Small should be no greater than 100 microseconds.

Implementation Note: This can be satisfied using a 32-bit 2's complement representation with a small of 2.0**(-14) — that is, 61 microseconds — and a range of ± 2.0**17 — that is, 131,072.0.

Implementation Advice: The value of Duration'Small should be no greater than 100 microseconds.

The time base for delay_relative_statements should be monotonic; it need not be the same time base as used for Calendar.Clock.

Implementation Advice: The time base for delay_relative_statements should be monotonic.

NOTES

33 A delay_relative_statement with a negative value of the delay_expression is equivalent to one with a zero value.

34 A delay_statement may be executed by the environment task; consequently delay_statements may be executed as part of the elaboration of a library_item or the execution of the main subprogram. Such statements delay the environment task (see 10.2).

35 A delay_statement is an abort completion point and a potentially blocking operation, even if the task is not actually blocked.

36 There is no necessary relationship between System.Tick (the resolution of the clock of package Calendar) and Duration'Small (the small of type Duration).

Ramification: The inaccuracy of the delay_statement has no relation to System.Tick. In particular, it is possible that the clock used for the delay_statement is less accurate than Calendar.Clock.
We considered making Tick a run-time-determined quantity, to allow for easier configurability. However, this would not be upward compatible, and the desired configurability can be achieved using functionality defined in Annex D, “Real-Time Systems”.

37 Additional requirements associated with delay statements are given in D.9, “Delay Accuracy”.

**Examples**

**Example of a relative delay statement:**

```
delay 3.0;  -- delay 3.0 seconds
```

**Example of a periodic task:**

```
declare
  use Ada.Calendar;
  Next_Time : Time := Clock + Period;
  -- Period is a global constant of type Duration
begin
  loop
    delay until Next_Time;
    ...  -- perform some actions
    Next_Time := Next_Time + Period;
  end loop;
end;
```

**Inconsistencies With Ada 83**

For programs that raise Time_Error on '+' or '-' in Ada 83, the exception might be deferred until a call on Split or Year_Number, or might not be raised at all (if the offending time is never Split after being calculated). This should not affect typical programs, since they deal only with times corresponding to the relatively recent past or near future.

**Extensions to Ada 83**

The syntax rule for delay_statement is modified to allow delay_until_statements.

```
{AI95-00351-01} The type Time may represent dates with year numbers outside of Year_Number. Therefore, the operations '+' and '-' need only raise Time_Error if the result is not representable in Time (or Duration); also, Split or Year will now raise Time_Error if the year number is outside of Year_Number. This change is intended to simplify the implementation of '+' and '-' (allowing them to depend on overflow for detecting when to raise Time_Error) and to allow local time zone information to be considered at the time of Split rather than Clock (depending on the implementation approach). For example, in a POSIX environment, it is natural for the type Time to be based on GMT, and the results of procedure Split (and the functions Year, Month, Day, and Seconds) to depend on local time zone information. In other environments, it is more natural for the type Time to be based on the local time zone, with the results of Year, Month, Day, and Seconds being pure functions of their input.
```

This paragraph was deleted.

```
{AI95-00351-01} We anticipate that implementations will provide child packages of Calendar to provide more explicit control over time zones and other environment-dependent time-related issues. These would be appropriate for standardization in a given environment (such as POSIX).
```

**Inconsistencies With Ada 95**

```
{AI95-00351-01} The upper bound of Year_Number has been changed to avoid a year 2100 problem. A program which expects years past 2099 to raise Constraint_Error will fail in Ada 2005. We don't expect there to be many programs which are depending on an exception to be raised. A program that uses Year_Number'Last as a magic number may also fail if values of Time are stored outside of the program. Note that the lower bound of Year_Number wasn't changed, because it is not unusual to use that value in a constant to represent an unknown time.
```

**Wording Changes from Ada 95**

```
{8652/0002} {AI95-00171-01} Corrigendum: Clarified that Month, Day, and Seconds can raise Time_Error.
```

**9.6.1 Formatting, Time Zones, and other operations for Time**

**Static Semantics**

```
{AI95-00351-01} {AI95-00427-01} The following language-defined library packages exist:
```
package Ada.Calendar.Time_Zones is
   -- Time zone manipulation:
   type Time_Offset is range -28*60 .. 28*60;
   Reason: We want to be able to specify the difference between any two arbitrary time zones. You might think that 1440 (24 hours) would be enough, but there are places (like Tonga, which is UTC+13hr) which are more than 12 hours than UTC. Combined with summer time (known as daylight saving time in some parts of the world) – which switches opposite in the northern and southern hemispheres – and even greater differences are possible. We know of cases of a 26 hours difference, so we err on the safe side by selecting 28 hours as the limit.
   Unknown_Zone_Error : exception;
   function UTC_Time_Offset (Date : Time := Clock) return Time_Offset;
end Ada.Calendar.Time_Zones;

package Ada.Calendar.Arithmetic is
   -- Arithmetic on days:
   type Day_Count is range -366*(1+Year_Number'Last - Year_Number'First) .. 366*(1+Year_Number'Last - Year_Number'First);
   subtype Leap_Seconds_Count is Integer range -2047 .. 2047;
   Reason: The maximum number of leap seconds is likely to be much less than this, but we don’t want to reach the limit too soon if the earth’s behavior suddenly changes. We believe that the maximum number is 1612, based on the current rules, but that number is too weird to use here.
   procedure Difference (Left, Right : in Time;
                        Days : out Day_Count;
                        Seconds : out Duration;
                        Leap_Seconds : out Leap_Seconds_Count);
   function "+" (Left : Time; Right : Day_Count) return Time;
   function "+" (Left : Day_Count; Right : Time) return Time;
   function "-" (Left : Time; Right : Day_Count) return Time;
   function "-" (Left, Right : Time) return Day_Count;
end Ada.Calendar.Arithmetic;

with Ada.Calendar.Time_Zones;
package Ada.Calendar.Formatting is
   -- Day of the week:
   type Day_Name is (Monday, Tuesday, Wednesday, Thursday,
                     Friday, Saturday, Sunday);

function Image (Elapsed_Time : Duration; Include_Time_Fraction : Boolean := False) return String;

function Value (Elapsed_Time : String) return Duration;
end Ada.Calendar.Formatting;

{AI95-00351-01} Type Time_Offset represents the number of minutes difference between the implementation-defined time zone used by Calendar and another time zone.

function UTC_Time_Offset (Date : Time := Clock) return Time_Offset;

{AI95-00351-01} {AI05-0119-1} {AI05-0269-1} Returns, as a number of minutes, the result of subtracting the difference between the implementation-defined time zone of Calendar from, and UTC time, at the time Date. If the time zone of the Calendar implementation is unknown, then Unknown_Zone_Error is raised.

Ramification: {AI05-0119-1} In North America, the result will be negative; in Europe, the result will be zero or positive.

Discussion: The Date parameter is needed to take into account time differences caused by daylight-savings time and other time changes. This parameter is measured in the time zone of Calendar, if any, not necessarily the UTC time zone.

Other time zones can be supported with a child package. We don't define one because of the lack of agreement on the definition of a time zone.

The accuracy of this routine is not specified; the intent is that the facilities of the underlying target operating system are used to implement it.

procedure Difference (Left, Right : in Time; Days : out Day_Count; Seconds : out Duration; Leap_Seconds : out Leap_Seconds_Count);

{AI95-00351-01} {AI95-00427-01} Returns the difference between Left and Right. Days is the number of days of difference, Seconds is the remainder seconds of difference excluding leap seconds, and Leap_Seconds is the number of leap seconds. If Left < Right, then Seconds <= 0.0, Days <= 0, and Leap_Seconds <= 0. Otherwise, all values are nonnegative. The absolute value of Seconds is always less than 86 400.0. For the returned values, if Days = 0, then Seconds + Duration(Leap_Seconds) = Calendar."-" (Left, Right).

Discussion: Leap Seconds, if any, are not included in Seconds. However, Leap_Seconds should be included in calculations using the operators defined in Calendar, as is specified for "-" above.

function "+" (Left : Time; Right : Day_Count) return Time;
function "+" (Left : Day_Count; Right : Time) return Time;

{AI95-00351-01} Adds a number of days to a time value. Time_Error is raised if the result is not representable as a value of type Time.

function "-" (Left : Time; Right : Day_Count) return Time;

{AI95-00351-01} Subtracts a number of days from a time value. Time_Error is raised if the result is not representable as a value of type Time.

function "-" (Left, Right : Time) return Day_Count;

{AI95-00351-01} Subtracts two time values, and returns the number of days between them. This is the same value that Difference would return in Days.
function Day_of_Week (Date : Time) return Day_Name;

{AI95-00351-01} Returns the day of the week for Time. This is based on the Year, Month, and Day values of Time.

function Year       (Date : Time;
                        Time_Zone  : Time_Zones.Time_Offset := 0)
                      return Year_Number;

{AI95-00427-01} Returns the year for Date, as appropriate for the specified time zone offset.

function Month      (Date : Time;
                        Time_Zone  : Time_Zones.Time_Offset := 0)
                      return Month_Number;

{AI95-00427-01} Returns the month for Date, as appropriate for the specified time zone offset.

function Day        (Date : Time;
                        Time_Zone  : Time_Zones.Time_Offset := 0)
                      return Day_Number;

{AI95-00427-01} Returns the day number for Date, as appropriate for the specified time zone offset.

function Hour       (Date : Time;
                        Time_Zone  : Time_Zones.Time_Offset := 0)
                      return Hour_Number;

{AI95-00351-01} Returns the hour for Date, as appropriate for the specified time zone offset.

function Minute     (Date : Time;
                        Time_Zone  : Time_Zones.Time_Offset := 0)
                      return Minute_Number;

{AI95-00351-01} Returns the minute within the hour for Date, as appropriate for the specified time zone offset.

function Second     (Date : Time)
                      return Second_Number;

{AI95-00351-01} {AI95-00427-01} Returns the second within the hour and minute for Date.

function Sub_Second (Date : Time)
                      return Second_Duration;

{AI95-00351-01} {AI95-00427-01} Returns the fraction of second for Date (this has the same accuracy as Day_Duration). The value returned is always less than 1.0.

function Seconds_Of (Hour   : Hour_Number;
                         Minute : Minute_Number;
                         Second : Second_Number := 0;
                         Sub_Second : Second_Duration := 0.0)
                      return Day_Duration;

{AI95-00351-01} {AI95-00427-01} Returns a Day_Duration value for the combination of the given Hour, Minute, Second, and Sub_Second. This value can be used in Calendar.Time_Of as well as the argument to Calendar."+" and Calendar."-". If Seconds_Of is called with a Sub_Second value of 1.0, the value returned is equal to the value of Seconds_Of for the next second with a Sub_Second value of 0.0.
procedure Split (Seconds    : in  Day_Duration;
    Hour       : out Hour_Number;
    Minute     : out Minute_Number;
    Second     : out Second_Number;
    Sub_Second : out Second_Duration);

{AI95-00351-01} {AI95-00427-01} {AI05-0238-1} Splits Seconds into Hour, Minute, Second
and Sub_Second in such a way that the resulting values all belong to their respective subtypes.
The value returned in the Sub_Second parameter is always less than 1.0. If Seconds = 86400.0,
Split propagates Time_Error.

Ramification: There is only one way to do the split which meets all of the requirements.

Reason: {AI05-0238-1} If Seconds = 86400.0, one of the returned values would have to be out of its defined range
(either Sub_Second = 1.0 or Hour = 24 with the other value being 0). This doesn't seem worth breaking the invariants.

function Time_Of (Year       : Year_Number;
    Month      : Month_Number;
    Day        : Day_Number;
    Hour       : Hour_Number;
    Minute     : Minute_Number;
    Second     : Second_Number;
    Sub_Second : Second_Duration := 0.0;
    Leap_Second: Boolean := False;
    Time_Zone  : Time_Zones.Time_Offset := 0)
return Time;

{AI95-00351-01} {AI95-00427-01} If Leap_Second is False, returns a Time built from the date
and time values, relative to the specified time zone offset. If Leap_Second is True, returns the
Time that represents the time within the leap second that is one second later than the time
specified by the other parameters. Time_Error is raised if the parameters do not form a proper
date or time. If Time_Of is called with a Sub_Second value of 1.0, the value returned is equal
to the value of Time_Of for the next second with a Sub_Second value of 0.0.

Discussion: Time_Error should be raised if Leap_Second is True, and the date and time values do not represent the
second before a leap second. A leap second always occurs at midnight UTC, and is 23:59:60 UTC in ISO notation. So,
if the time zone is UTC and Leap_Second is True, if any of Hour /= 23, Minute /= 59, or Second /= 59, then
Time_Error should be raised. However, we do not say that, because other time zones will have different values where a
leap second is allowed.

function Time_Of (Year       : Year_Number;
    Month      : Month_Number;
    Day        : Day_Number;
    Seconds    : Day_Duration := 0.0;
    Leap_Second: Boolean := False;
    Time_Zone  : Time_Zones.Time_Offset := 0)
return Time;

{AI95-00351-01} {AI95-00427-01} If Leap_Second is False, returns a Time built from the date
and time values, relative to the specified time zone offset. If Leap_Second is True, returns the
Time that represents the time within the leap second that is one second later than the time
specified by the other parameters. Time_Error is raised if the parameters do not form a proper
date or time. If Time_Of is called with a Seconds value of 86_400.0, the value returned is equal
to the value of Time_Of for the next day with a Seconds value of 0.0.
procedure Split (Date       : in Time;
    Year       : out Year_Number;
    Month      : out Month_Number;
    Day        : out Day_Number;
    Hour       : out Hour_Number;
    Minute     : out Minute_Number;
    Second     : out Second_Number;
    Sub_Second : out Second_Duration;
    Leap_Second: out Boolean;
    Time_Zone  : in Time_Zones.Time_Offset := 0);

{AI95-00351-01} {AI95-00427-01} If Date does not represent a time within a leap second, splits Date into its constituent parts (Year, Month, Day, Hour, Minute, Second, Sub_Second), relative to the specified time zone offset, and sets Leap_Second to False. If Date represents a time within a leap second, set the constituent parts to values corresponding to a time one second earlier than that given by Date, relative to the specified time zone offset, and sets Leap_Seconds to True. The value returned in the Sub_Second parameter is always less than 1.0.

procedure Split (Date       : in Time;
    Year       : out Year_Number;
    Month      : out Month_Number;
    Day        : out Day_Number;
    Hour       : out Hour_Number;
    Minute     : out Minute_Number;
    Second     : out Second_Number;
    Sub_Second : out Second_Duration;
    Time_Zone  : in Time_Zones.Time_Offset := 0);

{AI95-00351-01} {AI95-00427-01} Splits Date into its constituent parts (Year, Month, Day, Second, Sub Second), relative to the specified time zone offset. The value returned in the Sub_Second parameter is always less than 1.0.

procedure Split (Date       : in Time;
    Year       : out Year_Number;
    Month      : out Month_Number;
    Day        : out Day_Number;
    Seconds    : out Day_Duration;
    Leap_Second: out Boolean;
    Time_Zone  : in Time_Zones.Time_Offset := 0);

{AI95-00351-01} {AI95-00427-01} If Date does not represent a time within a leap second, splits Date into its constituent parts (Year, Month, Day, Seconds), relative to the specified time zone offset, and sets Leap_Second to False. If Date represents a time within a leap second, set the constituent parts to values corresponding to a time one second earlier than that given by Date, relative to the specified time zone offset, and sets Leap_Seconds to True. The value returned in the Seconds parameter is always less than 86_400.0.

function Image (Date : Time;
    Include_Time_Fraction : Boolean := False;
    Time_Zone  : in Time_Zones.Time_Offset := 0) return String;

{AI95-00351-01} Returns a string form of the Date relative to the given Time_Zone. The format is "Year-Month-Day Hour:Minute:Second", where the Year is a 4-digit value, and all others are 2-digit values, of the functions defined in Calendar and Calendar.Formatting, including a leading zero, if needed. The separators between the values are a minus, another minus, a colon, and a single space between the Day and Hour. If Include_Time_Fraction is True, the integer part of Sub_Seconds*100 is suffixed to the string as a point followed by a 2-digit value.

Discussion: The Image provides a string in ISO 8601 format, the international standard time format. Alternative representations allowed in ISO 8601 are not supported here.
ISO 8601 allows 24:00:00 for midnight, and a seconds value of 60 for leap seconds. These are not allowed here (the routines mentioned above cannot produce those results).

**Ramification:** The fractional part is truncated, not rounded. It would be quite hard to define the result with proper rounding, as it can change all of the values of the image. Values can be rounded up by adding an appropriate constant (0.5 if Include_Time_Fraction is False, 0.005 otherwise) to the time before taking the image.

```ada
function Value (Date : String; Time_Zone  : Time_Zones.Time_Offset := 0) return Time;
```

**{AI95-00351-01}** Returns a Time value for the image given as Date, relative to the given time zone. Constraint_Error is raised if the string is not formatted as described for Image, or the function cannot interpret the given string as a Time value.

**Discussion:** **{AI05-0005-1}** The intent is that the implementation enforce the same range rules on the string as the appropriate function Time_Of, except for the hour, so “cannot interpret the given string as a Time value” happens when one of the values is out of the required range. For example, "2005-08-31 24:00:0024:0:0" should raise Constraint_Error (the hour is out of range).

```ada
function Image (Elapsed_Time : Duration; Include_Time_Fraction : Boolean := False) return String;
```

**{AI95-00351-01}** Returns a string form of the Elapsed Time. The format is "Hour:Minute:Second", where all values are 2-digit values, including a leading zero, if needed. The separators between the values are colons. If Include_Time_Fraction is True, the integer part of Sub_Seconds*100 is suffixed to the string as a point followed by a 2-digit value. If Elapsed_Time < 0.0, the result is Image (abs Elapsed Time, Include Time Fraction) prefixed with a minus sign. If abs Elapsed Time represents 100 hours or more, the result is implementation-defined.

**Implementation defined:** The result of Calendar.Formatting.Image if its argument represents more than 100 hours.

**Implementation Note:** This cannot be implemented (directly) by calling Calendar.Formatting.Split, since it may be out of the range of Day_Duration, and thus the number of hours may be out of the range of Hour_Number.

If a Duration value can represent more then 100 hours, the implementation will need to define a format for the return of Image.

```ada
function Value (Elapsed_Time : String) return Duration;
```

**{AI95-00351-01}** Returns a Duration value for the image given as Elapsed Time. Constraint_Error is raised if the string is not formatted as described for Image, or the function cannot interpret the given string as a Duration value.

**Discussion:** The intent is that the implementation enforce the same range rules on the string as the appropriate function Time_Of, except for the hour, so “cannot interpret the given string as a Time value” happens when one of the values is out of the required range. For example, "10:23:60" should raise Constraint_Error (the seconds value is out of range).

**Implementation Advice**

**{AI95-00351-01}** An implementation should support leap seconds if the target system supports them. If leap seconds are not supported, Difference should return zero for Leap_Seconds, Split should return False for Leap_Second, and Time_Of should raise Time_Error if Leap_Second is True.

**Implementation Advice:** Leap seconds should be supported if the target system supports them. Otherwise, operations in Calendar.Formatting should return results consistent with no leap seconds.

**Discussion:** An implementation can always support leap seconds when the target system does not; indeed, this isn't particularly hard (all that is required is a table of when leap seconds were inserted). As such, leap second support isn't “impossible or impractical” in the sense of 1.1.3. However, for some purposes, it may be important to follow the target system's lack of leap second support (if the target is a GPS satellite, which does not use leap seconds, leap second support would be a handicap to work around). Thus, this Implementation Advice should be read as giving permission to not support leap seconds on target systems that don't support leap seconds. Implementers should use the needs of their customers to determine whether or not support leap seconds on such targets.
NOTES
38 {AI95-00351-01} The implementation-defined time zone of package Calendar may, but need not, be the local time zone. UTC_Time_Offset always returns the difference relative to the implementation-defined time zone of package Calendar. If UTC_Time_Offset does not raise Unknown_Zone_Error, UTC time can be safely calculated (within the accuracy of the underlying time-base).

Discussion: {AI95-00351-01} The time in the time zone known as Greenwich Mean Time (GMT) is generally very close to UTC time; for most purposes they can be treated the same. GMT is the time based on the rotation of the Earth; UTC is the time based on atomic clocks, with leap seconds periodically inserted to realign with GMT (because most human activities depend on the rotation of the Earth). At any point in time, there will be a sub-second difference between GMT and UTC.

39 {AI95-00351-01} Calling Split on the results of subtracting Duration(UTC_Time_Offset*60) from Clock provides the components (hours, minutes, and so on) of the UTC time. In the United States, for example, UTC_Time_Offset will generally be negative.

Discussion: This is an illustration to help specify the value of UTC_Time_Offset. A user should pass UTC_Time_Offset as the Time_Zone parameter of Split, rather than trying to make the above calculation.

Extensions to Ada 95

39.1 {AI95-00351-01} {AI95-00428-01} Packages Calendar.Time_Zones, Calendar.Arithmetic, and Calendar.Formatting are new.

Inconsistencies With Ada 2005

91.c.3 {AI05-0238-1} Correction: Defined that Split for Seconds raises Time_Error for a value of exactly 86400.0, rather than breaking some invariant or raising some other exception. Ada 2005 left this unspecified; a program that depended on what some implementation does might break, but such a program is not portable anyway.

Wording Changes from Ada 2005

91.d.3 {AI05-0119-1} Correction: Clarified the sign of UTC_Time_Offset.

9.7 Select Statements

[There are four forms of the select_statement. One form provides a selective wait for one or more select_alternatives. Two provide timed and conditional entry calls. The fourth provides asynchronous transfer of control.]

Syntax

select_statement ::= selective_accept |
                    timed_entry_call |
                    conditional_entry_call |
                    asynchronous_select

Examples

Example of a select statement:

select
  accept Driver_Awake_Signal;
or
  delay 30.0*Seconds;
  Stop_The_Train;
end select;

Extensions to Ada 83

4.a Asynchronous_select is new.
9.7.1 Selective Accept

[This form of the select_statement allows a combination of waiting for, and selecting from, one or more alternatives. The selection may depend on conditions associated with each alternative of the selective_accept. ]

Syntax

```
selective_accept ::= 
  select 
  [guard] 
  select_alternative 
  [ or 
    [guard] 
    select_alternative ] 
  [ else 
    sequence_of_statements ]
end select;

guard ::= when condition =>

select_alternative ::= 
  accept_alternative 
  | delay_alternative 
  | terminate_alternative
accept_alternative ::= 
  accept_statement [sequence_of_statements]
delay_alternative ::= 
  delay_statement [sequence_of_statements]
terminate_alternative ::= terminate;
```

A selective_accept shall contain at least one accept_alternative. In addition, it can contain:

- a terminate_alternative (only one); or
- one or more delay_alternatives; or
- an else part (the reserved word else followed by a sequence_of_statements).

These three possibilities are mutually exclusive.

Legality Rules

If a selective_accept contains more than one delay_alternative, then all shall be delay_relative_statements, or all shall be delay_until_statements for the same time type.

Reason: This simplifies the implementation and the description of the semantics.

Dynamic Semantics

A select_alternative is said to be open if it is not immediately preceded by a guard, or if the condition of its guard evaluates to True. It is said to be closed otherwise.

For the execution of a selective_accept, any guard conditions are evaluated; open alternatives are thus determined. For an open delay_alternative, the delay_expression is also evaluated. Similarly, for an open accept_alternative for an entry of a family, the entry_index is also evaluated. These evaluations are performed in an arbitrary order, except that a delay_expression or entry_index is not evaluated until after evaluating the corresponding condition, if any. Selection and execution of one open alternative, or of the
else part, then completes the execution of the `selective_accept`; the rules for this selection are described below.

Open `accept_alternatives` are first considered. Selection of one such alternative takes place immediately if the corresponding entry already has queued calls. If several alternatives can thus be selected, one of them is selected according to the entry queuing policy in effect (see 9.5.3 and D.4). When such an alternative is selected, the selected call is removed from its entry queue and the `handled_sequence_of_statements` (if any) of the corresponding `accept_statement` is executed; after the rendezvous completes any subsequent `sequence_of_statements` of the alternative is executed. If no selection is immediately possible (in the above sense) and there is no else part, the task blocks until an open alternative can be selected.

Selection of the other forms of alternative or of an else part is performed as follows:

- An open `delay_alternative` is selected when its expiration time is reached if no `accept_alternative` or other `delay_alternative` can be selected prior to the expiration time. If several `delay_alternatives` have this same expiration time, one of them is selected according to the queuing policy in effect (see D.4); the default queuing policy chooses arbitrarily among the `delay_alternatives` whose expiration time has passed.
- The else part is selected and its `sequence_of_statements` is executed if no `accept_alternative` can immediately be selected; in particular, if all alternatives are closed.
- `{AI05-0299-1}` An open `terminate_alternative` is selected if the conditions stated at the end of subclause 9.3 are satisfied.

**Ramification:** In the absence of a `requeue_statement`, the conditions stated are such that a `terminate_alternative` cannot be selected while there is a queued entry call for any entry of the task. In the presence of requeues from a task to one of its subtasks, it is possible that when a `terminate_alternative` of the subtask is selected, requeued calls (for closed entries only) might still be queued on some entry of the subtask. `Tasking_Error` will be propagated to such callers, as is usual when a task completes while queued callers remain.

The exception `Program_Error` is raised if all alternatives are closed and there is no else part.

**NOTES**

40 A `selective_accept` is allowed to have several open `delay_alternatives`. A `selective_accept` is allowed to have several open `accept_alternatives` for the same entry.

**Example of a task body with a selective accept:**

```ada
task body Server is
  Current_Work_Item : Work_Item;
begin
  loop
    select
      accepting Next_Work_Item(WI : in Work_Item)
      do
        Current_Work_Item := WI;
      end;
      Process_Work_Item(Current_Work_Item);
    or
      accepting Shut_Down
      exit; -- Premature shut down requested
    or
      terminating; -- Normal shutdown at end of scope
    end select;
  end loop;
end Server;
```

**Wording Changes from Ada 83**

24.a The name of `selective_wait` was changed to `selective_accept` to better describe what is being waited for. We kept `select_alternative` as is, because `selective_accept_alternative` was too easily confused with `accept_alternative.`
9.7.2 Timed Entry Calls

{AI95-00345-01} [A timed_entry_call issues an entry call that is cancelled if the call (or a requeue-with-abort of the call) is not selected before the expiration time is reached. A procedure call may appear rather than an entry call for cases where the procedure might be implemented by an entry. ]

Syntax

timed_entry_call ::= select entry_call_alternative or delay_alternative end select;

{AI95-00345-01} entry_call_alternative ::= procedure_or_entry_call entry_call_statement [sequence_of_statements]

{AI95-00345-01} procedure_or_entry_call ::= procedure_call_statement | entry_call_statement

Legality Rules

{AI95-00345-01} If a procedure_call_statement is used for a procedure_or_entry_call, the procedure_name or procedure_prefix of the procedure_call_statement shall statically denote an entry renamed as a procedure or (a view of) a primitive subprogram of a limited interface whose first parameter is a controlling parameter (see 3.9.2).

Reason: This would be a confusing way to call a procedure, so we only allow it when it is possible that the procedure is actually an entry. We could have allowed formal subprograms here, but we didn’t because we’d have to allow all formal subprograms, and it would increase the difficulty of generic code sharing.

We say “statically denotes” because an access-to-subprogram cannot be primitive, and we don’t have anything like access-to-entry. So only names of entries or procedures are possible.

Static Semantics

{AI95-00345-01} {AI05-0291-1} If a procedure_call_statement is used for a procedure_or_entry_call, and the procedure is implemented by an entry, then the procedure_name, or procedure_prefix and possibly the first parameter of the procedure_call_statement, determine the target object of the call and the entry to be called.

Discussion: The above says “possibly the first parameter”, because Ada allows entries to be renamed and passed as formal subprograms. In those cases, the task or protected object is implicit in the name of the routine; otherwise the object is an explicit parameter to the call.

Dynamic Semantics

{AI95-00345-01} For the execution of a timed_entry_call, the entry_name, procedure_name, or procedure_prefix, and any actual parameters are evaluated, as for a simple entry call (see 9.5.3) or procedure call (see 6.4). The expiration time (see 9.6) for the call is determined by evaluating the delay_expression of the delay_alternative. If the call is an entry call or a call on a procedure implemented by an entry, the entry call is then issued. Otherwise, the call proceeds as described in 6.4 for a procedure call, followed by the sequence of statements of the entry_call_alternative; the sequence_of_statements of the delay_alternative is ignored.

If the call is queued (including due to a requeue-with-abort), and not selected before the expiration time is reached, an attempt to cancel the call is made. If the call completes due to the cancellation, the optional
sequence_of_statements of the delay_alternative is executed; if the entry call completes normally, the optional sequence_of_statements of the entry_call_alternative is executed.

5.a/2 This paragraph was deleted. Ramification: \{AI95-00345-01\} The fact that the syntax calls for an entry_call_statement means that this fact is used in overload resolution. For example, if there is a procedure X and an entry X (both with no parameters), then "select X;..." is legal, because overload resolution knows that the entry is the one that was meant.

Examples

6 Example of a timed entry call:

7 select Controller.Request(Medium)(Some_Item);
    or delay 45.0;
    -- controller too busy, try something else
end select;

Wording Changes from Ada 83

7.a/3 \{AI05-0299-1\} This subclause comes before the one for Conditional Entry Calls, so we can define conditional entry calls in terms of timed entry calls.

Incompatibilities With Ada 95

7.b/3 \{AI95-00345-01\} \{AI05-0005-1\} A procedure call can be used as the entry_call_alternative in a timed or conditional entry call, if the procedure might actually be an entry. Since the fact that something is an entry could be used in resolving these calls in Ada 95, it is possible for timed or conditional entry calls that resolved in Ada 95 to be ambiguous in Ada 2005. That could happen if both an entry and procedure with the same name and profile exist, which should be rare.

9.7.3 Conditional Entry Calls

1/2 \{AI95-00345-01\} A conditional_entry_call issues an entry call that is then cancelled if it is not selected immediately (or if a requeue-with-abort of the call is not selected immediately). A procedure call may appear rather than an entry call for cases where the procedure might be implemented by an entry.

1.a To be honest: In the case of an entry call on a protected object, it is OK if the entry is closed at the start of the corresponding protected action, so long as it opens and the call is selected before the end of that protected action (due to changes in the Count attribute).

Syntax

2 conditional_entry_call ::= select entry_call_alternative else sequence_of_statements end select;

Dynamic Semantics

3 The execution of a conditional_entry_call is defined to be equivalent to the execution of a timed_entry_call with a delay_alternative specifying an immediate expiration time and the same sequence_of_statements as given after the reserved word else.

NOTES

41 A conditional_entry_call may briefly increase the Count attribute of the entry, even if the conditional call is not selected.
Examples

Example of a conditional entry call:

```ada
procedure Spin(R : in Resource) is
begin
  loop
    select
      R.Seize;
    return;
    else
      null;  -- busy waiting
    end select;
  end loop;
end;
```

Wording Changes from Ada 83

{AI05-0299-1} This subclause comes after the one for Timed Entry Calls, so we can define conditional entry calls in terms of timed entry calls. We do that so that an "expiration time" is defined for both, thereby simplifying the definition of what happens on a requeue-with-abort.

9.7.4 Asynchronous Transfer of Control

[An asynchronous select_statement provides asynchronous transfer of control upon completion of an entry call or the expiration of a delay.]

Syntax

```ada
asynchronous_select ::= 
  select
  triggering_alternative
  then abort
  abortable_part
end select;
```

```ada
triggering_alternative ::= triggering_statement [sequence_of_statements]
```

```ada
{AI95-00345-01} triggering_statement ::= 
  procedure_or_entry_call | entry_call_statement | delay_statement
```

```ada
abortable_part ::= sequence_of_statements
```

Dynamic Semantics

{AI95-00345-01} For the execution of an asynchronous_select whose triggering_statement is a procedure_or_entry_call--entry_call_statement, the entry_name, procedure_name, or procedure_prefix, and actual parameters are evaluated as for a simple entry call (see 9.5.3) or procedure call (see 6.4). If the call is an entry call or a call on a procedure implemented by an entry, and the entry call is issued. If the entry call is queued (or requeued-with-abort), then the abortable_part is executed. [If the entry call is selected immediately, and never requeued-with-abort, then the abortable_part is never started.] If the call is on a procedure that is not implemented by an entry, the call proceeds as described in 6.4, followed by the sequence_of_statements of the triggering_alternative; the abortable_part is never started).

For the execution of an asynchronous_select whose triggering_statement is a delay_statement, the delay_expression is evaluated and the expiration time is determined, as for a normal delay_statement. If the expiration time has not already passed, the abortable_part is executed.
If the abortable_part completes and is left prior to completion of the triggering_statement, an attempt to cancel the triggering_statement is made. If the attempt to cancel succeeds (see 9.5.3 and 9.6), the asynchronous_select is complete.

If the triggering_statement completes other than due to cancellation, the abortable_part is aborted (if started but not yet completed — see 9.8). If the triggering_statement completes normally, the optional sequence_of_statements of the triggering_alternative is executed after the abortable_part is left.

Discussion: We currently don't specify when the by-copy in out parameters are assigned back into the actuals. We considered requiring that to happen after the abortable_part is left. However, that doesn't seem useful enough to justify possibly overspecifying the implementation approach, since some of the parameters are passed by reference anyway.

In an earlier description, we required that the sequence_of_statements of the triggering_alternative execute after aborting the abortable_part, but before waiting for it to complete and finalize, to provide more rapid response to the triggering event in case the finalization was unbounded. However, various reviewers felt that this created unnecessary complexity in the description, and a potential for undesirable concurrency (and nondeterminism) within a single task. We have now reverted to simpler, more deterministic semantics, but anticipate that further discussion of this issue might be appropriate during subsequent reviews. One possibility is to leave this area implementation defined, so as to encourage experimentation. The user would then have to assume the worst about what kinds of actions are appropriate for the sequence_of_statements of the triggering_alternative to achieve portability.

Examples

Example of a main command loop for a command interpreter:

```ada
go
loop
  select
    Terminal.Wait_For_Interrupt;
    Put_Line("Interrupted");
  then abort
    -- This will be abandoned upon terminal interrupt
    Put_Line("->");
    Get_Line(Command, Last);
    Process_Command(Command(1..Last));
  end select;
end loop;
```

Example of a time-limited calculation:

```ada
go
select
  delay 5.0;
  Put_Line("Calculation does not converge");
then abort
  -- This calculation should finish in 5.0 seconds;
  -- if not, it is assumed to diverge.
  Horribly_Complicated_Recursive_Function(X, Y);
end select;
```

Extensions to Ada 83

Asynchronous_select is new.

Extensions to Ada 95

| A95-00345-01 | A procedure can be used as the triggering_statement of an asynchronous_select, if the procedure might actually be an entry.

9.8 Abort of a Task - Abort of a Sequence of Statements

[An abort_statement causes one or more tasks to become abnormal, thus preventing any further interaction with such tasks. The completion of the triggering_statement of an asynchronous_select causes a sequence_of_statements to be aborted.]
Syntax

abort_statement ::= abort task_name {, task_name};

Name Resolution Rules

Each task_name is expected to be of any task type[; they need not all be of the same task type.]

Dynamic Semantics

For the execution of an abort_statement, the given task_names are evaluated in an arbitrary order. Each named task is then aborted, which consists of making the task abnormal and aborting the execution of the corresponding task_body, unless it is already completed.

Ramification: \{AI95-00114-01\} Note that aborting those tasks is not defined to be an abort-deferred operation. Therefore, if one of the named tasks is the task executing the abort_statement, or if the task executing the abort_statement depends on one of the named tasks, then it is possible for the execution of the abort_statement to be aborted, thus leaving some of the tasks unaborted. This allows the implementation to use either a sequence of calls to an “abort task” run-time system\(\text{RTS}\) primitive, or a single call to an “abort list of tasks” run-time system\(\text{RTS}\) primitive.

When the execution of a construct is aborted (including that of a task_body or of a sequence_of_statements), the execution of every construct included within the aborted execution is also aborted, except for executions included within the execution of an abort-deferred operation; the execution of an abort-deferred operation continues to completion without being affected by the abort; the following are the abort-deferred operations:

- a protected action;
- waiting for an entry call to complete (after having initiated the attempt to cancel it — see below);
- waiting for the termination of dependent tasks;
- the execution of an Initialize procedure as the last step of the default initialization of a controlled object;
- the execution of a Finalize procedure as part of the finalization of a controlled object;
- an assignment operation to an object with a controlled part.

[The last three of these are discussed further in 7.6.]

Reason: Deferring abort during Initialize and finalization allows, for example, the result of an allocator performed in an Initialize operation to be assigned into an access object without being interrupted in the middle, which would cause storage leaks. For an object with several controlled parts, each individual Initialize is abort-deferred. Note that there is generally no semantic difference between making each Finalize abort-deferred, versus making a group of them abort-deferred, because if the task gets aborted, the first thing it will do is complete any remaining finalizations. Individual objects are finalized prior to an assignment operation (if nonlimited controlled) and as part of Unchecked_Deallocation.

Ramification: Abort is deferred during the entire assignment operation to an object with a controlled part, even if only some subcomponents are controlled. Note that this says “assignment operation,” not ”assignment_statement.” Explicit calls to Initialize, Finalize, or Adjust are not abort-deferred.

When a master is aborted, all tasks that depend on that master are aborted.

The order in which tasks become abnormal as the result of an abort_statement or the abort of a sequence_of_statements is not specified by the language.

If the execution of an entry call is aborted, an immediate attempt is made to cancel the entry call (see 9.5.3). If the execution of a construct is aborted at a time when the execution is blocked, other than for an entry call, at a point that is outside the execution of an abort-deferred operation, then the execution of the construct completes immediately. For an abort due to an abort_statement, these immediate effects occur before the execution of the abort_statement completes. Other than for these immediate cases, the execution of a construct that is aborted does not necessarily complete before the abort_statement.
completes. However, the execution of the aborted construct completes no later than its next *abort completion point* (if any) that occurs outside of an abort-deferred operation; the following are abort completion points for an execution:

- the point where the execution initiates the activation of another task;
- the end of the activation of a task;
- the start or end of the execution of an entry call, *accept_statement*, *delay_statement*, or *abort_statement*;

**Ramification:** Although the abort completion point doesn't occur until the end of the entry call or *delay_statement*, these operations might be cut short because an abort attempts to cancel them.

- the start of the execution of a *select_statement*, or of the *sequence_of_statements* of an *exception_handler*.

**Reason:** The start of an *exception_handler* is considered an abort completion point simply because it is easy for an implementation to check at such points.

**Implementation Note:** Implementations may of course check for abort more often than at each abort completion point; ideally, a fully preemptive implementation of abort will be provided. If preemptive abort is not supported in a given environment, then supporting the checking for abort as part of subprogram calls and loop iterations might be a useful option.

### Bounded (Run-Time) Errors

**AI05-0264-1** An attempt to execute an *asynchronous_select* as part of the execution of an abort-deferred operation is a bounded error. Similarly, an attempt to create a task that depends on a master that is included entirely within the execution of an abort-deferred operation is a bounded error. In both cases, Program_Error is raised if the error is detected by the implementation; otherwise, the operations proceed as they would outside an abort-deferred operation, except that an abort of the *abortable_part* or the created task might or might not have an effect.

**Reason:** An *asynchronous_select* relies on an abort of the *abortable_part* to effect the asynchronous transfer of control. For an *asynchronous_select* within an abort-deferred operation, the abort might have no effect.

Creating a task dependent on a master included within an abort-deferred operation is considered an error, because such tasks could be aborted while the abort-deferred operation was still progressing, undermining the purpose of abort-deferral. Alternatively, we could say that such tasks are abort-deferred for their entire execution, but that seems too easy to abuse. Note that task creation is already a bounded error in protected actions, so this additional rule only applies to local task creation as part of Initialize, Finalize, or Adjust.

### Erroneous Execution

If an assignment operation completes prematurely due to an abort, the assignment is said to be *disrupted*; the target of the assignment or its parts can become abnormal, and certain subsequent uses of the object can be erroneous, as explained in 13.9.1.

**NOTES**

42 An *abort_statement* should be used only in situations requiring unconditional termination.

43 A task is allowed to abort any task it can name, including itself.

44 Additional requirements associated with abort are given in D.6, “Preemptive Abort”.

**Wording Changes from Ada 83**

**AI05-0299-1** This *subclause* has been rewritten to accommodate the concept of aborting the execution of a construct, rather than just of a task.
9.9 Task and Entry Attributes

Dynamic Semantics

For a prefix T that is of a task type [(after any implicit dereference)], the following attributes are defined:

T'Callable  
Yields the value True when the task denoted by T is callable, and False otherwise; a task is callable unless it is completed or abnormal. The value of this attribute is of the predefined type Boolean.

T'Terminated  
Yields the value True if the task denoted by T is terminated, and False otherwise. The value of this attribute is of the predefined type Boolean.

For a prefix E that denotes an entry of a task or protected unit, the following attribute is defined. This attribute is only allowed within the body of the task or protected unit, but excluding, in the case of an entry of a task unit, within any program unit that is, itself, inner to the body of the task unit.

E'Count  
Yields the number of calls presently queued on the entry E of the current instance of the unit. The value of this attribute is of the type universal_integer.

NOTES
45 For the Count attribute, the entry can be either a single entry or an entry of a family. The name of the entry or entry family can be either a direct_name or an expanded name.
46 Within task units, algorithms interrogating the attribute E'Count should take precautions to allow for the increase of the value of this attribute for incoming entry calls, and its decrease, for example with timed_entry_calls. Also, a conditional_entry_call may briefly increase this value, even if the conditional call is not accepted.
47 Within protected units, algorithms interrogating the attribute E'Count in the entry_barrier for the entry E should take precautions to allow for the evaluation of the condition of the barrier both before and after queuing a given caller.

9.10 Shared Variables

Static Semantics

If two different objects, including nonoverlapping parts of the same object, are independently addressable, they can be manipulated concurrently by two different tasks without synchronization. Any two nonoverlapping objects are independently addressable if either object is specified as independently addressable (see C.6). Otherwise, two nonoverlapping objects are independently addressable except when they are both parts of a composite object for which a nonconfirming value is specified for any of the following representation aspects: (record) Layout, Component_Size, Pack, Atomic, or Convention; in this case it is unspecified whether the parts are independently addressable. Normally, any two nonoverlapping objects are independently addressable. However, if packing, record layout, or Component_Size is specified for a given composite object, then it is implementation defined whether or not two nonoverlapping parts of that composite object are independently addressable.

This paragraph was deleted. Implementation defined: Whether or not two nonoverlapping parts of a composite object are independently addressable, in the case where packing, record layout, or Component_Size is specified for the object.

Implementation Note: {AI05-0229-1} Independent addressability is the only high level semantic effect of aspect pragma Pack. If two objects are independently addressable, the implementation should allocate them in such a way that each can be written by the hardware without writing the other. For example, unless the user asks for it, it is generally not feasible to choose a bit-packed representation on a machine without an atomic bit field insertion instruction, because there might be tasks that update neighboring subcomponents concurrently, and locking operations on all subcomponents is generally not a good idea.

Even if Pack or one of the other above-mentioned aspects is specified, subcomponents should still be updated independently if the hardware efficiently supports it.
An atomic object (including atomic components) is always independently addressable from any other nonoverlapping object. Any aspect specification or representation item which would prevent this from being true should be rejected, notwithstanding what this Standard says elsewhere. Note, however, that the components of an atomic object are not necessarily atomic.

Dynamic Semantics

Separate tasks normally proceed independently and concurrently with one another. However, task interactions can be used to synchronize the actions of two or more tasks to allow, for example, meaningful communication by the direct updating and reading of variables shared between the tasks.] The actions of two different tasks are synchronized in this sense when an action of one task signals an action of the other task; an action A1 is defined to signal an action A2 under the following circumstances:

- If A1 and A2 are part of the execution of the same task, and the language rules require A1 to be performed before A2;
- If A1 is the action of an activator that initiates the activation of a task, and A2 is part of the execution of the task that is activated;
- If A1 is part of the activation of a task, and A2 is the action of waiting for completion of the activation;
- If A1 is part of the execution of a task, and A2 is the action of waiting for the termination of the task;
- If A1 is the termination of a task T, and A2 is either the evaluation of the expression \( T'\text{Terminated} \) that results in True, or a call to \( \text{Ada.Task_Identification.Is_Terminated} \) with an actual parameter that identifies T and a result of True (see C.7.1);
- If A1 is the action of issuing an entry call, and A2 is part of the corresponding execution of the appropriate entry_body or accept_statement;

Ramification: Evaluating the entry_index of an accept_statement is not synchronized with a corresponding entry call, nor is evaluating the entry barrier of an entry_body.

- If A1 is part of the execution of an accept_statement or entry_body, and A2 is the action of returning from the corresponding entry call;
- If A1 is part of the execution of a protected procedure body or entry_body for a given protected object, and A2 is part of a later execution of an entry_body for the same protected object;

Reason: The underlying principle here is that for one action to "signal" a second, the second action has to follow a potentially blocking operation, whose blocking is dependent on the first action in some way. Protected procedures are not potentially blocking, so they can only be "signalers," they cannot be signaled.

Ramification: Protected subprogram calls are not defined to signal one another, which means that such calls alone cannot be used to synchronize access to shared data outside of a protected object.

Reason: The point of this distinction is so that on multiprocessors with inconsistent caches, the caches only need to be refreshed at the beginning of an entry body, and forced out at the end of an entry body or protected procedure that leaves an entry open. Protected function calls, and protected subprogram calls for entryless protected objects do not require full cache consistency. Entryless protected objects are intended to be treated roughly like atomic objects — each operation is indivisible with respect to other operations (unless both are reads), but such operations cannot be used to synchronize access to other nonvolatile shared variables.

- If A1 signals some action that in turn signals A2.

Erroneous Execution

Given an action of assigning to an object, and an action of reading or updating a part of the same object (or of a neighboring object if the two are not independently addressable), then the execution of the actions is erroneous unless the actions are sequential. Two actions are sequential if one of the following is true:

- One action signals the other;
• Both actions occur as part of the execution of the same task;

  **Reason:** Any two actions of the same task are sequential, even if one does not signal the other because they can be executed in an “arbitrary” (but necessarily equivalent to some “sequential”) order.

• Both actions occur as part of protected actions on the same protected object, and at most one of the actions is part of a call on a protected function of the protected object.

  **Reason:** Because actions within protected actions do not always imply signaling, we have to mention them here explicitly to make sure that actions occurring within different protected actions of the same protected object are sequential with respect to one another (unless both are part of calls on protected functions).

  **Ramification:** It doesn't matter whether or not the variable being assigned is actually a subcomponent of the protected object; globals can be safely updated from within the bodies of protected procedures or entries.

\{AI05-0229-1\}  **Aspect**

An `Atomic` or `aspect Atomic` Component may also be specified to ensure that certain reads and updates are sequential — see C.6.

  **Ramification:** If two actions are “sequential” it is known that their executions don't overlap in time, but it is not necessarily specified which occurs first. For example, all actions of a single task are sequential, even though the exact order of execution is not fully specified for all constructs.

  **Discussion:** Note that if two assignments to the same variable are sequential, but neither signals the other, then the program is not erroneous, but it is not specified which assignment ultimately prevails. Such a situation usually corresponds to a programming mistake, but in some (rare) cases, the order makes no difference, and for this reason this situation is not considered erroneous nor even a bounded error. In Ada 83, this was considered an “incorrect order dependence” if the “effect” of the program was affected, but “effect” was never fully defined. In Ada 95, this situation represents a potential nonportability, and a friendly compiler might want to warn the programmer about the situation, but it is not considered an error. An example where this would come up would be in gathering statistics as part of referencing some information, where the assignments associated with statistics gathering don't need to be ordered since they are just accumulating aggregate counts, sums, products, etc.

**Wording Changes from Ada 95**

\{8652/0031\} \{AI95-00118-01\}  **Corrigendum:** Clarified that a task T2 can rely on values of variables that are updated by another task T1, if task T2 first verifies that T1'Terminated is True.

**Wording Changes from Ada 2005**

\{AI05-0009-1\} \{AI05-0201-1\}  **Correction:** Revised the definition of independent addressability to exclude conforming representation clauses and to require that atomic and independent objects always have independent addressability. This should not change behavior that the user sees for any Ada program, so it is not an inconsistency.

\{AI05-0072-1\}  **Correction:** Corrected the wording of AI95-00118-01 to actually say what was intended (as described above).

### 9.11 Example of Tasking and Synchronization

**Examples**

The following example defines a buffer protected object to smooth variations between the speed of output of a producing task and the speed of input of some consuming task. For instance, the producing task might have the following structure:

```ada
task Producer;
{AI95-00433-01} task body Producer is
    Person : Person_Name; -- see 3.10.1; Char : Character;
begin
    loop
        ... -- simulate arrival of the next customer produce the next character Char Buffer.Append_Wait(Person)
        Write(Char);
        exit when Person = null Char = ASCII.EOT;
    end loop
end Producer;
```

and the consuming task might have the following structure:

```ada
task Consumer;
{AI95-00433-01} task body Consumer is
    Person : Person_Name; Char : Character;
begin
    loop
        Buffer.Remove_first_Wait(Person) Read(Char);
        exit when Person = null Char = ASCII.EOT;
        ... -- simulate serving a customer, consume the character Char
    end loop;
end Consumer;
```

{AI95-00433-01} The buffer object contains an internal array pool of person names and characters, managed in a round-robin fashion. The array pool has two indices, an In_INDEX denoting the index space for the next input person name character and an Out_INDEX denoting the index space for the next output person name character.

{AI95-00433-01} The Buffer is defined as an extension of the Synchronized_Queue interface (see 3.9.4), and as such promises to implement the abstraction defined by that interface. By doing so, the Buffer can be passed to the Transfer class-wide operation defined for objects of a type covered by Queue'Class.

```ada
protected Buffer is new Synchronized_Queue with -- see 3.9.4
    entry Append_Wait(Person : in Person_Name) Read(C : out Character);
    entry Remove_First_Wait(Person : out Person_Name);
    function Cur_Count return Natural;
    function Max_Count return Natural;
    procedure Append_First(Person : in Person_Name) Write(C : in Character);
private
    Pool : Person_Name_Array String (1 .. 100);
    Count : Natural := 0;
    In_INDEX, Out_INDEX : Positive := 1;
end Buffer;

protected body Buffer is
    entry Append_Wait(Person : in Person_Name) Write(C : in Character)
when Count < Pool'Length is
    begin
        Append(Person); Pool(In_INDEX) := C;

   return Buffer.Count;
end Cur_Count;

function Max_Count return Natural is
begin
   return Pool'Length;
end Max_Count;
end Buffer;
10 Program Structure and Compilation Issues

{AI05-0299-1} [The overall structure of programs and the facilities for separate compilation are described in this clause section. A program is a set of partitions, each of which may execute in a separate address space, possibly on a separate computer.

Glossary entry: A program is a set of partitions, each of which may execute in a separate address space, possibly on a separate computer. A partition consists of a set of library units.

Glossary entry: A partition is a part of a program. Each partition consists of a set of library units. Each partition may run in a separate address space, possibly on a separate computer. A program may contain just one partition. A distributed program typically contains multiple partitions, which can execute concurrently.

As explained below, a partition is constructed from library units. Syntactically, the declaration of a library unit is a library_item, as is the body of a library unit. An implementation may support a concept of a program library (or simply, a “library”), which contains library_items and their subunits. Library units may be organized into a hierarchy of children, grandchildren, and so on.]

{AI05-0299-1} This clause section has two subclauses: 10.1, “Separate Compilation” discusses compile-time issues related to separate compilation. 10.2, “Program Execution” discusses issues related to what is traditionally known as “link time” and “run time” — building and executing partitions.

Language Design Principles

We should avoid specifying details that are outside the domain of the language itself. The standard is intended (at least in part) to promote portability of Ada programs at the source level. It is not intended to standardize extra-language issues such as how one invokes the compiler (or other tools), how one's source is represented and organized, version management, the format of error messages, etc.

The rules of the language should be enforced even in the presence of separate compilation. Using separate compilation should not make a program less safe.

It should be possible to determine the legality of a compilation unit by looking only at the compilation unit itself and the compilation units upon which it depends semantically. As an example, it should be possible to analyze the legality of two compilation units in parallel if they do not depend semantically upon each other.

On the other hand, it may be necessary to look outside that set in order to generate code — this is generally true for generic instantiation and inlining, for example. Also on the other hand, it is generally necessary to look outside that set in order to check Post-Compilation Rules.

See also the “generic contract model” Language Design Principle of 12.3, “Generic Instantiation”.

Wording Changes from Ada 83

{AI05-0299-1} The clause section organization mentioned above is different from that of RM83.

10.1 Separate Compilation

[ A program unit is either a package, a task unit, a protected unit, a protected entry, a generic unit, or an explicitly declared subprogram other than an enumeration literal. Certain kinds of program units can be separately compiled. Alternatively, they can appear physically nested within other program units.

The text of a program can be submitted to the compiler in one or more compilations. Each compilation is a succession of compilation_units. A compilation_unit contains either the declaration, the body, or a renaming of a program unit.] The representation for a compilation is implementation-defined.

Implementation defined: The representation for a compilation.

Ramification: Some implementations might choose to make a compilation be a source (text) file. Others might allow multiple source files to be automatically concatenated to form a single compilation. Others still may represent the source in a nontextual form such as a parse tree. Note that the RM95 does not even define the concept of a source file.

Note that a protected subprogram is a subprogram, and therefore a program unit. An instance of a generic unit is a program unit.
A protected entry is a program unit, but protected entries cannot be separately compiled.

A library unit is a separately compiled program unit, and is always a package, subprogram, or generic unit. Library units may have other (logically nested) library units as children, and may have other program units physically nested within them. A root library unit, together with its children and grandchildren and so on, form a subsystem.

Implementation Permissions

An implementation may impose implementation-defined restrictions on compilations that contain multiple compilation_units.

Implementation defined: Any restrictions on compilations that contain multiple compilation_units.

Discussion: For example, an implementation might disallow a compilation that contains two versions of the same compilation unit, or that contains the declarations for library packages P1 and P2, where P1 precedes P2 in the compilation but P1 has a with_clause that mentions P2.

Wording Changes from Ada 83

The interactions between language issues and environmental issues are left open in Ada 95. The environment concept is new. In Ada 83, the concept of the program library, for example, appeared to be quite concrete, although the rules had no force, since implementations could get around them simply by defining various mappings from the concept of an Ada program library to whatever data structures were actually stored in support of separate compilation. Indeed, implementations were encouraged to do so.

In RM83, it was unclear which was the official definition of “program unit.” Definitions appeared in RM83-5, 6, 7, and 9, but not 12. Placing it here seems logical, since a program unit is sort of a potential compilation unit.

10.1.1 Compilation Units - Library Units

A library_item is a compilation unit that is the declaration, body, or renaming of a library unit. Each library unit (except Standard) has a parent unit, which is a library package or generic library package. A library unit is a child of its parent unit. The root library units are the children of the predefined library package Standard.

Ramification: Standard is a library unit.

Syntax

```
compilation ::= {compilation_unit}
compilation_unit ::= context_clause library_item
| context_clause subunit
library_item ::= [private] library_unit_declaration
| library_unit_body
| [private] library_unit_renaming_declaration
library_unit_declaration ::= subprogram_declaration | package_declaration
| generic_declaration | generic_instantiation
library_unit_renaming_declaration ::= package_renaming_declaration
| generic_renaming_declaration
| subprogram_renaming_declaration
library_unit_body ::= subprogram_body | package_body
parent_unit_name ::= name
```
An overridingIndicator is not allowed in a subprogram_declaration, generic_instantiation, or subprogram_renaming_declaration that declares a library unit.

Reason: All of the listed items syntactically include overriding_indicator, but a library unit can never override anything. A majority of the ARG thought that allowing not overriding in that case would be confusing instead of helpful.

A library unit is a program unit that is declared by a library_item. When a program unit is a library unit, the prefix “library” is used to refer to it (or “generic library” if generic), as well as to its declaration and body, as in “library procedure”, “library package_body”, or “generic library package”. The term compilation_unit is used to refer to a compilation_unit. When the meaning is clear from context, the term is also used to refer to the library_item of a compilation_unit or to the proper body of a subunit [(that is, the compilation_unit without the context_clause and the separate (parent_unit_name))].

Discussion: In this example:

```ada
with Ada.Text_IO;
package P is
... end P;
```
the term “compilation_unit” can refer to this text: “with Ada.Text_IO; package P is ... end P;” or to this text: “package P is ... end P;”. We use this shorthand because it corresponds to common usage.

We like to use the word “unit” for declaration-plus-body things, and “item” for declaration or body separately (as in declarative_item). The terms “compilation_unit,” “compilation_unit,” and “subunit” are exceptions to this rule. We considered changing “compilation_unit,” “compilation_unit” to “compilation_item,” “compilation_item,” respectively, but we decided not to.

The parent declaration of a library_item (and of the library unit) is the declaration denoted by the parent_unit_name, if any, of the defining_program_unit_name of the library_item. If there is no parent_unit_name, the parent declaration is the declaration of Standard, the library_item is a root library_item, and the library unit (renaming) is a root library unit (renaming). The declaration and body of Standard itself have no parent declaration. The parent unit of a library_item or library unit is the library unit declared by its parent declaration.

Discussion: The declaration and body of Standard are presumed to exist from the beginning of time, as it were. There is no way to actually write them, since there is no syntactic way to indicate lack of a parent. An attempt to compile a package Standard would result in Standard.Standard.

Reason: Library units (other than Standard) have “parent declarations” and “parent units”. Subunits have “parent bodies”. We didn't bother to define the other possibilities: parent body of a library unit, parent declaration of a subunit, parent unit of a subunit. These are not needed, and might get in the way of a correct definition of “child.”

[The children of a library unit occur immediately within the declarative region of the declaration of the library unit.] The ancestors of a library unit are itself, its parent, its parent's parent, and so on. [(Standard is an ancestor of every library unit,)] The descendant relation is the inverse of the ancestor relation.

Reason: These definitions are worded carefully to avoid defining subunits as children. Only library units can be children.

We use the unadorned term “ancestors” here to concisely define both “ancestor unit” and “ancestor declaration.”

A library_unit_declaration or a library_unit_renaming_declaration is private if the declaration is immediately preceded by the reserved word private; it is otherwise public. A library unit is private or public according to its declaration. The public descendants of a library unit are the library unit itself, and the public descendants of its public children. Its other descendants are private descendants.

Discussion: The first concept defined here is that a library_item is either public or private (not in relation to anything else — it’s just a property of the library unit). The second concept is that a library_item is a public descendant or private descendant of a given ancestor. A given library_item can be a public descendant of one of its ancestors, but a private descendant of some other ancestor.

A subprogram declared by a subprogram_body (as opposed to a subprogram_declaration) is always public, since the syntax rules disallow the reserved word private on a body.
Note that a private library unit is a public descendant of itself, but a private descendant of its parent. This is because it is visible outside itself — its privateness means that it is not visible outside its parent.

Private children of Standard are legal, and follow the normal rules. It is intended that implementations might have some method for taking an existing environment, and treating it as a package to be “imported” into another environment, treating children of Standard in the imported environment as children of the imported package.

**Ramification:** Suppose we have a public library unit A, a private library unit A.B, and a public library unit A.B.C. A.B.C is a public descendant of itself and of A.B, but a private descendant of A; since A.B is private to A, we don't allow A.B.C to escape outside A either. This is similar to the situation that would occur with physical nesting, like this:

```ada
package A is
  private
  package B is
    package C is
      private
      end C;
    end B;
  end B;
end A;
```

Here, A.B.C is visible outside itself and outside A.B, but not outside A. (Note that this example is intended to illustrate the visibility of program units from the outside; the visibility within child units is not quite identical to that of physically nested units, since child units are nested after their parent's declaration.)

{[AI95-00217-06]} For each library package declaration in the environment, there is an implicit declaration of a limited view of that library package. The limited view of a package contains:

- For each nested package declaration occurring immediately within the visible part, a declaration of the limited view of that package, with the same defining program unit name.
- For each type declaration occurring immediately within the visible part that is not an incomplete type declaration, an incomplete view of the type with no discriminant part; if the type declaration is tagged, then the view is a tagged incomplete view.

**Reason:** The incomplete view of a type does not have a discriminant part even if the type declaration does have one. This is necessary because semantic analysis (and the associated dependence on with clauses) would be necessary to determine the types of the discriminants.

**Discussion:** No incomplete views of incomplete types are included in the limited view. The rules of 3.10.1 ensure that the completion of any visible incomplete type is declared in the same visible part, so such an incomplete view would simply be redundant.

**Ramification:** The limited view does not include package instances and their contents. Semantic analysis of a unit (and dependence on its with clauses) would be needed to determine the contents of an instance.

The limited view of a library package declaration is private if that library package declaration is immediately preceded by the reserved word `private`.

There is no syntax for declaring limited views of packages, because they are always implicit. The implicit declaration of a limited view of a library package [is not the declaration of a library unit (the library package declaration is)]; nonetheless, it is a library item. The implicit declaration of the limited view of a library package forms an (implicit) compilation unit whose context clause is empty.

**A library package declaration is the completion of the declaration of its limited view.**

**To be honest:** This is notwithstanding the rule in 3.11.1 that says that implicit declarations don't have completions.

**Reason:** This rule explains where to find the completions of the incomplete views defined by the limited view.

The parent unit of a library item shall be a [library] package or generic [library] package.
If a defining_program_unit_name of a given declaration or body has a parent_unit_name, then the given declaration or body shall be a library_item. The body of a program unit shall be a library_item if and only if the declaration of the program unit is a library_item. In a library_unit_renaming_declaration, the [(old)] name shall denote a library_item.

Discussion: We could have allowed nested program units to be children of other program units; their semantics would make sense. We disallow them to keep things simpler and because they wouldn't be particularly useful.

{AI95-00217-06} A parent_unit_name [(which can be used within a defining_program_unit_name of a library_item and in the separate clause of a subunit), and each of its prefixes, shall not denote a renaming_declaration. [On the other hand, a name that denotes a library_unit_renaming_declaration is allowed in a nonlimited_with_clause with_clause and other places where the name of a library unit is allowed.]

If a library package is an instance of a generic package, then every child of the library package shall either be itself an instance or be a renaming of a library unit.

Discussion: A child of an instance of a given generic unit will often be an instance of a (generic) child of the given generic unit. This is not required, however.

Reason: Instances are forbidden from having noninstance children for two reasons:
1. We want all source code that can depend on information from the private part of a library unit to be inside the "subsystem" rooted at the library unit. If an instance of a generic unit were allowed to have a noninstance as a child, the source code of that child might depend on information from the private part of the generic unit, even though it is outside the subsystem rooted at the generic unit.
2. Disallowing noninstance children simplifies the description of the semantics of children of generic packages.

{AI05-0004-1} A child of a generic library package shall either be itself a generic unit or be a renaming of some other child of the same generic unit. The renaming of a child of a generic package shall occur only within the declarative region of the generic package.

A child of a parent generic package shall be instantiated or renamed only within the declarative region of the parent generic.

{AI95-00331-01} For each child_declaration or renaming of a generic unit as a child of some parent generic package P, there is a corresponding declaration C nested immediately within each instance of P. For the purposes of this rule, if a child C itself has a child D, each corresponding declaration for C has a corresponding child D of the parent. The corresponding declaration for a child within an instance is visible only within the scope of a with_clause that mentions the (original) child generic unit.

Implementation Note: Within the child, like anything nested in a generic unit, one can make up-level references to the current instance of its parent, and thereby gain access to the formal parameters of the parent, to the types declared in the parent, etc. This “nesting” model applies even within the generic_formal_part of the child, as it does for a generic child of a nongeneric unit.

Ramification: Suppose P is a generic library package, and P.C is a generic child of P. P.C can be instantiated inside the declarative region of P. Outside P, P.C can be mentioned only in a with_clause. Conceptually, an instance I of P is a package that has a nested generic unit called I.C. Mentioning P.C in a with_clause allows I.C to be instantiated. I need not be a library unit, and the instantiation of I.C need not be a library unit. If I is a library unit, and an instance of I.C is a child of I, then this instance has to be called something other than C.

A library subprogram shall not override a primitive subprogram.

Reason: This prevents certain obscure anomalies. For example, if a library subprogram were to override a subprogram declared in its parent package, then in a compilation unit that depends indirectly on the library subprogram, the library subprogram could hide the overridden operation from all visibility, but the library subprogram itself would not be visible.

Note that even without this rule, such subprograms would be illegal for tagged types, because of the freezing rules.

The defining name of a function that is a compilation unit shall not be an operator_symbol.

Reason: Since overloading is not permitted among compilation units, it seems unlikely that it would be useful to define one as an operator. Note that a subunit could be renamed within its parent to be an operator.
Static Semantics

A subprogram_renaming_declaration that is a library_unit_renaming_declaration is a renaming-as-declaration, not a renaming-as-body.

[There are two kinds of dependences among compilation units:]

- The semantic dependences (see below) are the ones needed to check the compile-time rules across compilation unit boundaries; a compilation unit depends semantically on the other compilation units needed to determine its legality. The visibility rules are based on the semantic dependences.

- The elaboration dependences (see 10.2) determine the order of elaboration of library_items.

Discussion: Don't confuse these kinds of dependences with the run-time dependences among tasks and masters defined in 9.3, “Task Dependence - Termination of Tasks”.

{AI95-00217-06} A library_item depends semantically upon its parent declaration. A subunit depends semantically upon its parent body. A library_unit_body depends semantically upon the corresponding library_unit_declaration, if any. The declaration of the limited view of a library_package depends semantically upon the declaration of the limited view of its parent. The declaration of a library_package depends semantically upon the declaration of its limited view. A compilation unit depends semantically upon each library_item mentioned in a with_clause of the compilation unit. In addition, if a given compilation unit contains an attribute_reference of a type defined in another compilation unit, then the given compilation unit depends semantically upon the other compilation unit. The semantic dependence relationship is transitive.

Discussion: The “if any” in the third sentence is necessary because library subprograms are not required to have a subprogram_declaration.

To be honest: If a given compilation unit contains a choice_parameter_specification, then the given compilation unit depends semantically upon the declaration of Ada.Exceptions.

If a given compilation unit contains a pragma with an argument of a type defined in another compilation unit, then the given compilation unit depends semantically upon the other compilation unit.

Discussion: For example, a compilation unit containing X'Address depends semantically upon the declaration of package System. For the Address attribute, this fixes a hole in Ada 83. Note that in almost all cases, the dependence will need to exist due to with_clauses, even without this rule. Hence, the rule has very little effect on programmers.

Note that the semantic dependence does not have the same effect as a with_clause; in order to denote a declaration in one of those packages, a with_clause will generally be needed.

Note that no special rule is needed for an attribute_definition_clause, since an expression after use will require semantic dependence upon the compilation unit containing the type_declaration of interest.

{AI95-00217-06} Unlike a full view of a package, a limited view does not depend semantically on units mentioned in with_clauses of the compilation unit that defines the package. Formally, this is achieved by saying that the limited view has an empty context_clause. This is necessary so that they can be useful for their intended purpose: allowing mutual dependences between packages. The lack of semantic dependence limits the contents of a limited view to the items that can be determined solely from the syntax of the source of the package, without any semantic analysis. That allows it to be created without the semantic dependences of a full package.

Dynamic Semantics

{AI95-00217-06} The elaboration of the declaration of the limited view of a package has no effect.

NOTES

A simple program may consist of a single compilation unit. A compilation need not have any compilation units; for example, its text can consist of pragmas.

Ramification: Such pragmas cannot have any arguments that are names, by a previous rule of this subclause. A compilation can even be entirely empty, which is probably not useful.

Some interesting properties of the three kinds of dependence: The elaboration dependences also include the semantic dependences, except that subunits are taken together with their parents. The semantic dependences partly determine the
order in which the compilation units appear in the environment at compile time. At run time, the order is partly
determined by the elaboration dependences.

The model whereby a child is inside its parent's declarative region, after the parent's declaration, as explained in 8.1,
has the following ramifications:

- The restrictions on “early” use of a private type (RM83-7.4.1(4)) or a deferred constant (RM83-7.4.3(2)) do
  not apply to uses in child units, because they follow the full declaration.

- A library subprogram is never primitive, even if its profile includes a type declared immediately within the
  parent's package_specification, because the child is not declared immediately within the same
  package_specification as the type (so it doesn't declare a new primitive subprogram), and because the child
  is forbidden from overriding an old primitive subprogram. It is immediately within the same declarative
  region, but not the same package_specification. Thus, for a tagged type, it is not possible to call a child
  subprogram in a dispatching manner. (This is also forbidden by the freezing rules.) Similarly, it is not
  possible for the user to declare primitive subprograms of the types declared in the declaration of Standard,
  such as Integer (even if the rules were changed to allow a library unit whose name is an operator symbol).

- When the parent unit is “used” the simple names of the with'd child units are directly visible (see 8.4, “Use
  Clauses”).

- When a parent body with's its own child, the defining name of the child is directly visible, and the parent
  body is not allowed to include a declaration of a homograph of the child unit immediately within the
  declarative_part of the body (RM83-8.3(17)).

Note that “declaration of a library unit” is different from “library_unit_declaration” — the former includes
subprogram_body. Also, we sometimes really mean “declaration of a view of the child unit immediately within the
library_unit_renaming_declaration.

The visibility rules generally imply that the renamed view of a library_unit_renaming_declaration has to be mentioned
in a with_clause of the library_unit_renaming_declaration.

To be honest: The real rule is that the renamed library unit has to be visible in the library_unit_renaming_declaration.

Reason: In most cases, “has to be visible” means there has to be a with_clause. However, it is possible in obscure
cases to avoid the need for a with_clause; in particular, a compilation unit such as “package P.Q renames P;” is legal
with no with_clauses (though not particularly interesting). ASCII is physically nested in Standard, and so is not a
library unit, and cannot be renamed as a library unit.

2 The designator of a library function cannot be an operator_symbol, but a nonlibrary renaming_declaration is allowed to
rename a library function as an operator. Within a partition, two library subprograms are required to have distinct names
and hence cannot overload each other. However, renaming declarations are allowed to define overloaded names for such
subprograms, and a locally declared subprogram is allowed to overload a library subprogram. The expanded name
Standard.L can be used to denote a root library unit L (unless the declaration of Standard is hidden) since root library unit
declarations occur immediately within the declarative region of package Standard.

Examples of library units:

```ada
package Rational_Numbers.IO is -- public child of Rational_Numbers, see 7.1
  procedure Put(R : in Rational);
  procedure Get(R : out Rational);
end Rational_Numbers.IO;

private procedure Rational_Numbers.Reduce(R : in out Rational); -- private child of Rational_Numbers
end Rational_Numbers;
with Rational_Numbers.Reduce; -- refer to a private child
package body Rational_Numbers is
...
end Rational_Numbers;
with Rational_Numbers.IO; use Rational_Numbers;
with Ada.Text_io; -- see A.10
procedure Main is -- a root library procedure
  R : Rational;
begin
  R := 5/3; -- construct a rational number, see 7.1
  Ada.Text_IO.Put("The answer is: ");
  IO.Put(R);
  Ada.Text_IO.New_Line;
end Main;
```

Examples
with Rational_Numbers.IO;
package Rational_IO renames Rational_Numbers.IO;

-- a library unit renaming declaration

Each of the above library_items can be submitted to the compiler separately.

Discussion: Example of a generic package with children:

generic
  type Element is private;
  with function Image(E : Element) return String;
package Generic_Bags is
  type Bag is limited private; -- A bag of Elements.
  procedure Add(B : in out Bag; E : Element);
  function Bag_Image(B : Bag) return String;
private
  type Bag is ...;
end Generic_Bags;

generic
package Generic_Bags.Generic_Iterators is
  ... -- various additional operations on Bags.
end Generic_Bags.Generic_Iterators;

A package that instantiates the above generic units:

with Generic_Bags;
with Generic_Bags.Generic_Iterators;
package My_Abstraction is
  type My_Type is ...;
  function Image(X : My_Type) return String;
package Bags_Of_My_Type is new Generic_Bags(My_Type, Image);
package Iterators_Of_Bags_Of_My_Type is new Bags_Of_My_Type.Generic_Iterators;
end My_Abstraction;

In the above example, Bags_Of_My_Type has a nested generic unit called Generic_Iterators. The second with_clause makes that nested unit visible.

Here we show how the generic body could depend on one of its own children:

with Generic_Bags.Generic_Iterators;
package body Generic_Bags is
  procedure Add(B : in out Bag; E : Element) is ... end Add;
  package Iters is new Generic_Iterators;
function Bag_Image(B : Bag) return String is
  Buffer : String(1..10_000);
  Last : Integer := 0;
  procedure Append_Image(E : in Element) is
    Im : constant String := Image(E);
    begin
      if Last /= 0 then -- Insert a comma.
        Last := Last + 1;
        Buffer(Last) := ',';
      end if;
      Buffer(Last+1 .. Last+Im'Length) := Im;
      Last := Last + Im'Length;
      end Append_Image;
  procedure Append_All is new Iters.Iterate(Append_Image);
begin
  Append_All(B);
  return Buffer(1..Last);
end Bag_Image;
end Generic_Bags;

Extensions to Ada 83

The syntax rule for library_item is modified to allow the reserved word private before a library_unit_declaration.

Children (other than children of Standard) are new in Ada 95.

Library unit renaming is new in Ada 95.
Wording Changes from Ada 83

Standard is considered a library unit in Ada 95. This simplifies the descriptions, since it implies that the parent of each library unit is a library unit. (Standard itself has no parent, of course.) As in Ada 83, the language does not define any way to recompile Standard, since the name given in the declaration of a library unit is always interpreted in relation to Standard. That is, an attempt to compile a package Standard would result in Standard.Standard.

Extensions to Ada 95

{AI95-00217-06} The concept of a limited view is new. Combined with limited_with clauses (see 10.1.2), they facilitate construction of mutually recursive types in multiple packages.

Wording Changes from Ada 95

{AI95-00331-01} Clarified the wording so that a grandchild generic unit will work as expected.

Wording Changes from Ada 2005

{AI05-0108-1} {AI05-0129-1} Correction: Clarified the wording so that it is clear that limited views of types never have discriminants and never are of incomplete types.

10.1.2 Context Clauses - With Clauses

[A context_clause is used to specify the library_items whose names are needed within a compilation unit.]

Language Design Principles

The reader should be able to understand a context_clause without looking ahead. Similarly, when compiling a context_clause, the compiler should not have to look ahead at subsequent context_items, nor at the compilation unit to which the context_clause is attached. (We have not completely achieved this.)

{AI95-00217-06} A ripple effect occurs when the legality of a compilation unit could be affected by adding or removing an otherwise unneeded with_clause on some compilation unit on which the unit depends, directly or indirectly. We try to avoid ripple effects because they make understanding and maintenance more difficult. However, ripple effects can occur because of direct visibility (as in child units); this seems impossible to eliminate. The ripple effect for with_clauses is somewhat similar to the Beaujolais effect (see 8.4) for use_clauses, which we also try to avoid.

Syntax

context_clause ::= {context_item}

context_item ::= with_clause | use_clause

{AI95-00217-06} {AI95-00262-01} with_clause ::= limited_with_clause | nonlimited_with_clause with library_unit_name {, library_unit_name};

limited_with_clause ::= [limited] private with library_unit_name {, library_unit_name};

nonlimited_with_clause ::= [private] with library_unit_name {, library_unit_name};

Discussion: [AI95-00217-06] A limited_with_clause makes a limited view of a unit visible.

{AI95-00262-01} A with_clause containing the reserved word private is called a private with clause. It can be thought of as making items visible only in the private part, although it really makes items visible everywhere except the visible part. It can be used both for documentation purposes (to say that a unit is not used in the visible part), and to allow access to private units that otherwise would be prohibited.

Name Resolution Rules

The scope of a with_clause that appears on a library_unit_declaration or library_unit_renaming_declaration consists of the entire declarative region of the declaration[, which includes all children and subunits]. The scope of a with_clause that appears on a body consists of the body[, which includes all subunits].

Discussion: {AI95-00262-01} Suppose a nonprivate with_clause of a public library unit mentions one of its private siblings. (This is only allowed on the body of the public library unit.) We considered making the scope of that with_clause not include the visible part of the public library unit. (This would only matter for a subprogram_body, since those are the only kinds of body that have a visible part, and only if the subprogram_body completes a subprogram_declaration, since otherwise the with_clause would be illegal.) We did not put in such a rule for two reasons: (1) It would complicate the wording of the rules, because we would have to split each with_clause into pieces, in order to correctly handle “with P, Q,” where P is public and Q is private. (2) The conformance rules prevent any problems. It doesn't matter if a type name in the spec of the body denotes the completion of a private_type_declaration.

A with_clause also affects visibility within subsequent use_clauses and pragmas of the same context_clause, even though those are not in the scope of the with_clause.

Discussion: {AI95-00217-06} A library_item (and the corresponding library unit) is named mentioned in a with_clause if it is denoted by a library_unit_name or a prefix in the with_clause. A library_item (and the corresponding library unit) is mentioned in a with_clause if it is named in the with_clause or if it is denoted by a prefix in the with_clause.

Legality Rules

Discussion: This rule violates the one-pass context_clauses Language Design Principle. We rationalize this by saying that at least that Language Design Principle works for legal compilation units.

Example:

```ada
package A is
end A;
```

```ada
package A.B is
end A.B;
```

```ada
private package A.B.C is
end A.B.C;
```

```ada
package A.B.C.D is
end A.B.C.D;
```

```ada
with A.B.C; -- (1)
```

```ada
private package A.B.X is
end A.B.X;
```
package A.B.Y is
end A.B.Y;

with A.B.C; -- (2)
package body A.B.Y is
end A.B.Y;

private with A.B.C; -- (3)
package A.B.Z is
end A.B.Z;

{AI95-00262-01} (1) is OK because it's a private child of A.B — it would be illegal if we made A.B.X a public child
of A.B. (2) is OK because it's the body of a child of A.B. (3) is OK because it's a child of A.B, and it is a private
with clause. It would be illegal to say "with A.B.C;" on any library item whose name does not start with “A.B”. Note
that mentioning A.B.C.D in a with clause automatically mentions A.B.C as well, so “with A.B.C.D;” is illegal in
the same places as “with A.B.C;”.

To be honest: {AI05-0005-1} {AI95-00262-01} For the purposes of this rule, if a subprogram body has no preceding
subprogram declaration, the subprogram body should be considered a declaration and not a body. Thus, it is illegal
for such a subprogram body to mention one of its siblings in a nonprivate with clause if the sibling is a private
library unit.

{AI95-00262-01} {AI05-0077-1} {AI05-0122-1} A name denoting a library item (or the corresponding
declaration for a child of a generic within an instance — see 10.1.1), if it library item that
is visible only
due to being mentioned in one or more with clauses that include the reserved word private, shall appear
only within:

• a private part;
• a body, but not within the subprogram specification of a library subprogram body;
• a private descendant of the unit on which one of these with clauses appear; or
• a pragma within a context clause.

Ramification: These rules apply only if all of the with clauses that mention the name include the reserved word
private. They do not apply if the name is mentioned in any with clause that does not include private.

Reason: {AI05-0077-1} These rules make the library item visible anywhere that is not visible outside the
subsystem rooted at the compilation unit having the private with clause, including private parts of packages nested in
the visible part, private parts of child packages, the visible part of private children, and context clause pragmas like
Elaborate_All.

We considered having the scope of a private with clause not include the visible part. However, that rule would mean
that moving a declaration between the visible part and the private part could change its meaning from one legal
interpretation to a different legal interpretation. For example:

package A is
    function B return Integer;
end A;

function B return Integer;
with A;
private with B;
package C is
    use A;
    V1 : Integer := B; -- (1)
private
    V2 : Integer := B; -- (2)
end C;

If we say that library subprogram B is not in scope in the visible part of C, then the B at (1) resolves to A.B, while (2)
resolves to library unit B. Simply moving a declaration could silently change its meaning. With the legality rule
defined above, the B at (1) is illegal. If the user really meant A.B, they still can say that.

{AI95-00217-06} [A library item mentioned in a limited with clause shall be the implicit declaration of
the limited view of a library package, not the declaration of a subprogram, generic unit, generic instance,
or a renaming.]

Proof: This is redundant because only such implicit declarations are visible in a limited with clause. See 10.1.6.

{AI95-00217-06} {AI95-00412-01} A limited with clause shall not appear on a library unit body,
subunit, or library unit renaming declaration.

18.a/2  **Reason:** {AI95-00412-01} We don't allow a **limited with clause** on a **library unit renaming declaration** because it would be useless and therefore probably is a mistake. A renaming cannot appear in a **limited with clause** (by the rule prior to this one), and a renaming of a limited view cannot appear in a **nonlimited with clause** (because the name would not be within the scope of a **with clause** denoting the package, see 8.5.3). Nor could it be the parent of another unit. That doesn't leave anywhere that the name of such a renaming could appear, so we simply make writing it illegal.

19/2  **AI95-00217-06**  A **limited with clause** that names a library package shall not appear:

20/3  • **AI95-00217-06**  **AI05-0040-1**  **AI05-0077-1**  **AI05-0262-1**  **AI05-0267-1**  **AI05-0307-1**  **AI05-0317-1**  **AI05-0401-1**  **AI05-0404-1**  **AI05-0406-1**  **AI05-0408-1**  **AI05-0410-1**  **AI05-0412-01**  **AI05-0414-02**  **AI05-0416-03**  **AI05-0418-04**  **AI05-0420-05**  **AI05-0422-06**  **AI05-0424-07**

**Reason:** We have to explicitly disallow

20.a/2

20.b/2

20.c/2

20.d/2

20.e/2

20.f/3

20.g/3

20.h/3

21/3  • **AI95-00217-06**  **AI05-0077-1**  **AI05-0262-1**  **AI05-0267-1**  **AI05-0307-1**  **AI05-0317-1**  **AI05-0401-1**  **AI05-0404-1**  **AI05-0406-1**  **AI05-0408-1**  **AI05-0410-1**  **AI05-0412-01**  **AI05-0414-02**  **AI05-0416-03**  **AI05-0418-04**  **AI05-0420-05**  **AI05-0422-06**  **AI05-0424-07**

**Reason:** Such a **limited with clause** could have no effect, and would be confusing. If it is within the scope of a **nonlimited with clause** for the same package is inherited from a parent unit or given, or if such a clause is in the **context clause**, the full view is available, which strictly provides more information than the limited view.

22/3  • **AI95-00217-06**  **AI05-0077-1**  **AI05-0262-1**  **AI05-0267-1**  **AI05-0307-1**  **AI05-0317-1**  **AI05-0401-1**  **AI05-0404-1**  **AI05-0406-1**  **AI05-0408-1**  **AI05-0410-1**  **AI05-0412-01**  **AI05-0414-02**  **AI05-0416-03**  **AI05-0418-04**  **AI05-0420-05**  **AI05-0422-06**  **AI05-0424-07**

**Reason:** This applies to **nonlimited with clauses** found in the same **context clause**, as well as **nonlimited with clauses** found on parent units.

22.a/3

22.b/3

22.c/3

22.d/3

22.e/3

22.f/3

22.g/3

**Reason:** This prevents visibility issues, where whether an entity is an incomplete or full view depends on how the name of the entity is written. The **limited with clause** cannot be useful, as we must have the full view available in the parent in order for the **use clause** to be legal.

NOTES

3  **AI95-00217-06**  A **library item** mentioned in a **nonlimited with clause with clause** of a compilation unit is visible within the compilation unit and hence acts just like an ordinary declaration. Thus, within a compilation unit that mentions its declaration, the name of a library package can be given in **use clauses** and can be used to form expanded names, a library subprogram can be called, and instances of a generic library unit can be declared. If a child of a parent generic package is mentioned in a **nonlimited with clause with clause**, then the corresponding declaration nested within each visible instance is visible within the compilation unit. Similarly, a **library item** mentioned in a **limited with clause of a compilation unit** is visible within the compilation unit and thus can be used to form expanded names.

23.a

23.b

**Ramification:** The rules given for **with clauses** are such that the same effect is obtained whether the name of a library unit is mentioned once or more than once by the applicable **with clauses**, or even within a given **with clause**.

If a **with clause** mentions a **library unit renaming declaration**, it only “mentions” the prefixes appearing explicitly in the **with clause** (and the renamed view itself); the **with clause** is not defined to mention the ancestors of the renamed entity. Thus, if X renames Y.Z, then “with X;” does not make the declarations of Y or Z visible. Note that this does not cause the dreaded visibility holes mentioned above.
Examples

\{AI95-00433-01\} \textbf{package} \texttt{Office} \textbf{is}
\texttt{end} \texttt{Office};

\{AI95-00433-01\} \textbf{with} \texttt{Ada.Strings.Unbounded};
\textbf{package} \texttt{Office.Locations} \textbf{is}
\quad \textbf{type} \texttt{Location} \textbf{is} \textbf{new} \texttt{Ada.Strings.Unbounded.Unbounded_String};
\texttt{end} \texttt{Office.Locations};

\{AI95-00433-01\} \textbf{limited with} \texttt{Office.Departments}; \textit{-- types are incomplete}
\textbf{private with} \texttt{Office.Locations}; \textit{-- only visible in private part}
\textbf{package} \texttt{Office.Employees} \textbf{is}
\quad \textbf{type} \texttt{Employee} \textbf{is} \textbf{private};
\quad \textbf{function} \texttt{Dept_Of} (\texttt{Emp} : \texttt{Employee}) \textbf{return} \texttt{access} \texttt{Departments.Department};
\quad \textbf{procedure} \texttt{Assign_Dept} (\texttt{Emp} : \texttt{in out} \texttt{Employee};
\quad \quad \texttt{Dept} : \texttt{access} \texttt{Departments.Department});
\quad \ldots
\quad \textbf{private}
\quad \textbf{type} \texttt{Employee} \textbf{is}
\quad \quad \textbf{record}
\quad \quad \quad \texttt{Dept} : \texttt{access} \texttt{Departments.Department};
\quad \quad \quad \texttt{Loc} : \texttt{Locations.Location};
\quad \quad \ldots
\quad \textbf{end} \texttt{record};
\texttt{end} \texttt{Office.Employees};

\{AI95-00433-01\} \textbf{limited with} \texttt{Office.Employees};
\textbf{package} \texttt{Office.Departments} \textbf{is}
\quad \textbf{type} \texttt{Department} \textbf{is} \textbf{private};
\quad \textbf{function} \texttt{Manager_Of} (\texttt{Dept} : \texttt{Department}) \textbf{return} \texttt{access} \texttt{Employees.Employee};
\quad \textbf{procedure} \texttt{Assign_Manager} (\texttt{Dept} : \texttt{in out} \texttt{Department};
\quad \quad \texttt{Mgr} : \texttt{access} \texttt{Employees.Employee});
\quad \ldots
\quad \textbf{end} \texttt{Office.Departments};

\{AI95-00433-01\} \textbf{The limited with clause} may be used to support mutually dependent abstractions that are split across multiple packages. In this case, an employee is assigned to a department, and a department has a manager who is an employee. If a with clause with the reserved word \texttt{private} appears on one library unit and mentions a second library unit, it provides visibility to the second library unit, but restricts that visibility to the private part and body of the first unit. The compiler checks that no use is made of the second unit in the visible part of the first unit.

Extensions to Ada 83

The syntax rule for with\_clause is modified to allow expanded name notation.
A use\_clause in a context\_clause may be for a package (or type) nested in a library package.

Wording Changes from Ada 83

The syntax rule for context\_clause is modified to more closely reflect the semantics. The Ada 83 syntax rule implies that the use\_clauses that appear immediately after a particular with\_clause are somehow attached to that with\_clause, which is not true. The new syntax allows a use\_clause to appear first, but that is prevented by a textual rule that already exists in Ada 83.

The concept of “scope of a with\_clause” (which is a region of text) replaces RM83’s notion of “apply to” (a with\_clause applies to a library\_item) The visibility rules are interested in a region of text, not in a set of compilation units.

No need to define “apply to” for use\_clauses. Their semantics are fully covered by the “scope (of a use\_clause)” definition in 8.4.

Incompatibilities With Ada 95

\{AI95-00220-01\} \textbf{Amendment Correction:} A subprogram body acting as a declaration cannot \texttt{with} a private child unit. This would allow public export of types declared in private child packages, and thus cannot be allowed. This was allowed by mistake in Ada 95; a subprogram that does this will now be illegal.
Extensions to Ada 95

31.g/2 {AI95-00217-06} limited_with_clauses are new. They make a limited view of a package visible, where all of the types in the package are incomplete. They facilitate construction of mutually recursive types in multiple packages.

31.h/3 {AI95-00262-01} {AI05-0077-1} The syntax rules for with_clause are modified to allow the reserved word private. Private with clauses do not allow the use of their library_item in the visible part of their compilation_unit. They also allow using private units in more locations than in Ada 95.

Incompatibilities With Ada 2005

31.i/3 {AI05-0040-1} Correction: Added missing rule that a limited with clause cannot name an ancestor unit. This is incompatible if an Ada 2005 program does this, but as this is a new Ada 2005 feature and the unintentionally allowed capability is not useful, the incompatibility is very unlikely to occur in practice.

Wording Changes from Ada 2005

31.j/3 {AI05-0077-1} Correction: Fixed wording so that we are not checking whether something in a context_clause is “within the scope of” something, as context_clauses are never included in anything’s scope. The intended meaning is unchanged, however.

31.k/3 {AI05-0122-1} Correction: Fixed wording so the rules for private with clauses also apply to ”sprouted” generic child units.

10.1.3 Subunits of Compilation Units

[Subunits are like child units, with these (important) differences: subunits support the separate compilation of bodies only (not declarations); the parent contains a body_stub to indicate the existence and place of each of its subunits; declarations appearing in the parent's body can be visible within the subunits.]

Syntax

body_stub ::= subprogram_body_stub | package_body_stub | task_body_stub | protected_body_stub

3/3 {AI95-00218-03} {AI05-0267-1} subprogram_body_stub ::= [overriding_indicator] _subprogram_specification is separate _[aspect_specification];

3.a Discussion: Although this syntax allows a parent_unit_name, that is disallowed by 10.1.1, “Compilation Units - Library Units”.

package_body_stub ::= _package body defining_identifier is separate _[aspect_specification];

task_body_stub ::= _task body defining_identifier is separate _[aspect_specification];

protected_body_stub ::= _protected body defining_identifier is separate _[aspect_specification];

7 subunit ::= separate (parent_unit_name) proper_body

Legality Rules

8/2 {AI95-00243-01} The parent body of a subunit is the body of the program unit denoted by its parent_unit_name. The term subunit is used to refer to a subunit and also to the proper_body of a subunit. The subunits of a program unit include any subunit that names that program unit as its parent, as well as any subunit that names such a subunit as its parent (recursively).
Reason: {AI95-00243-01} We want any rule that applies to a subunit to apply to a subunit of a subunit as well.

The parent body of a subunit shall be present in the current environment, and shall contain a corresponding body_stub with the same defining_identifier as the subunit.

Discussion: This can't be a Name Resolution Rule, because a subunit is not a complete context.

{AI05-0004-1} A package_body_stub shall be the completion of a package_declaration or generic_package_declaration; a task_body_stub shall be the completion of a task_declaration; a protected_body_stub shall be the completion of a protected_declaration.

In contrast, a subprogram_body_stub need not be the completion of a previous declaration, [in which case the _stub declares the subprogram]. If the _stub is a completion, it shall be the completion of a subprogram_declaration or generic_subprogram_declaration. The profile of a subprogram_body_stub that completes a declaration shall conform fully to that of the declaration.

Discussion: The part about subprogram_body_stubs echoes the corresponding rule for subprogram_bodies in 6.3, “Subprogram Bodies”.

A subunit that corresponds to a body_stub shall be of the same kind (package_, subprogram_, task_, or protected_) as the body_stub. The profile of a subprogram_body subunit shall be fully conformant to that of the corresponding body_stub.

A body_stub shall appear immediately within the declarative_part of a compilation unit body. This rule does not apply within an instance of a generic unit.

Discussion: This is a methodological restriction; that is, it is not necessary for the semantics of the language to make sense.

The defining_identifiers of all body_stubs that appear immediately within a particular declarative_part shall be distinct.

Post-Compilation Rules

For each body_stub, there shall be a subunit containing the corresponding proper_body.

NOTES

4 The rules in 10.1.4, “The Compilation Process” say that a body_stub is equivalent to the corresponding proper_body. This implies:

- Visibility within a subunit is the visibility that would be obtained at the place of the corresponding body_stub (within the parent body) if the context_clause of the subunit were appended to that of the parent body.
  
  Ramification: Recursively. Note that this transformation might make the parent illegal; hence it is not a true equivalence, but applies only to visibility within the subunit.

- The effect of the elaboration of a body_stub is to elaborate the subunit.
  
  Ramification: The elaboration of a subunit is part of its parent body's elaboration, whereas the elaboration of a child unit is not part of its parent declaration's elaboration.

  Ramification: A library_item that is mentioned in a with_clause of a subunit can be hidden (from direct visibility) by a declaration (with the same identifier) given in the subunit. Moreover, such a library_item can even be hidden by a declaration given within the parent body since a library unit is declared in its parent's declarative region; this however does not affect the interpretation of the with_clauses themselves, since only library_items are visible or directly visible in with_clauses.

  The body of a protected operation cannot be a subunit. This follows from the syntax rules. The body of a protected unit can be a subunit.

Examples

The package Parent is first written without subunits:

    package Parent is
      procedure Inner;
    end Parent;
with Ada.Text_IO;
package body Parent is
    Variable : String := "Hello, there.";
    procedure Inner is
        begin
            Ada.Text_IO.Put_Line(Variable);
        end Inner;
    end Parent;

The body of procedure Inner may be turned into a subunit by rewriting the package body as follows (with the declaration of Parent remaining the same):

package body Parent is
    Variable : String := "Hello, there.";
    procedure Inner is separate;
end Parent;

with Ada.Text_IO;
separate(Parent)
procedure Inner is
    begin
        Ada.Text_IO.Put_Line(Variable);
    end Inner;

---

10.1.4 The Compilation Process

Each compilation unit submitted to the compiler is compiled in the context of an environment declarative_part (or simply, an environment), which is a conceptual declarative_part that forms the outermost declarative region of the context of any compilation. At run time, an environment forms the declarative_part of the environment task of a partition (see 10.2, “Program Execution”).

Ramification: At compile time, there is no particular construct that the declarative region is considered to be nested within — the environment is the universe.

To be honest: The environment is really just a portion of a declarative_part, since there might, for example, be bodies that do not yet exist.

The declarative_items of the environment are library_items appearing in an order such that there are no forward semantic dependences. Each included subunit occurs in place of the corresponding stub. The visibility rules apply as if the environment were the outermost declarative region, except that with_-clauses are needed to make declarations of library units visible (see 10.1.2).

3/2 {AI95-00217-06} The mechanisms for creating an environment and for adding and replacing compilation units within an environment are implementation defined. The mechanisms for adding a compilation unit mentioned in a limited_with_clause to an environment are implementation defined.

Implementation defined: The mechanisms for creating an environment and for adding and replacing compilation units.

---

21
with Ada.Text_IO;
package body Parent is
    Variable : String := "Hello, there.";
    procedure Inner is
        begin
            Ada.Text_IO.Put_Line(Variable);
        end Inner;
    end Parent;

22 The body of procedure Inner may be turned into a subunit by rewriting the package body as follows (with the declaration of Parent remaining the same):

package body Parent is
    Variable : String := "Hello, there.";
    procedure Inner is separate;
end Parent;

23 with Ada.Text_IO;
separate(Parent)
procedure Inner is
    begin
        Ada.Text_IO.Put_Line(Variable);
    end Inner;

---

24.a Subunits of the same ancestor library unit are no longer restricted to have distinct identifiers. Instead, we require only that the full expanded names be distinct.

---

24

24.b2 {AI95-00218-03} An overriding_indicator (see 8.3.1) is allowed on a subprogram stub.

Wording Changes from Ada 95

24.c2 {AI95-00243-01} Clarified that a subunit of a subunit is still a subunit.

Wording Changes from Ada 95

24.d3 {AI05-0267-1} An optional aspect_specification can be used in a body_stub. This is described in 13.1.1.

---

10.1.3 Subunits of Compilation Units
Implementation defined: The mechanisms for adding a compilation unit mentioned in a limited_with_clause to an environment.

Ramification: The traditional model, used by most Ada 83 implementations, is that one places a compilation unit in the environment by compiling it. Other models are possible. For example, an implementation might define the environment to be a directory; that is, the compilation units in the environment are all the compilation units in the source files contained in the directory. In this model, the mechanism for replacing a compilation unit with a new one is simply to edit the source file containing that compilation unit.

Name Resolution Rules

{8652/0032} {AI95-00192-01} {AI05-0264-1} If a library_unit_body that is a subprogram_body is submitted to the compiler, it is interpreted only as a completion if a library_unit_declaration for a subprogram or a generic subprogram with the same defining_program_unit_name already exists in the environment for a subprogram other than an instance of a generic subprogram or for a generic subprogram (even if the profile of the body is not type conformant with that of the declaration); otherwise, the subprogram_body is interpreted as both the declaration and body of a library subprogram.

Ramification: The principle here is that a subprogram_body should be interpreted as only a completion if and only if it “might” be legal as the completion of some preexisting declaration, where “might” is defined in a way that does not require overload resolution to determine.

Hence, if the preexisting declaration is a subprogram_declaration or generic_subprogram_declaration, we treat the new subprogram_body as its completion, because it “might” be legal. If it turns out that the profiles don't fully conform, it's an error. In all other cases (the preexisting declaration is a package or a generic package, or an instance of a generic subprogram, or a renaming, or a “spec-less” subprogram, or in the case where there is no preexisting thing), the subprogram_body declares a new subprogram.

See also AI83-00266/09.

Legality Rules

When a compilation unit is compiled, all compilation units upon which it depends semantically shall already exist in the environment; the set of these compilation units shall be consistent in the sense that the new compilation unit shall not semantically depend (directly or indirectly) on two different versions of the same compilation unit, nor on an earlier version of itself.

Discussion: For example, if package declarations A and B both say “with X;”, and the user compiles a compilation unit that says “with A, B;”, then the A and B have to be talking about the same version of X.

Ramification: What it means to be a “different version” is not specified by the language. In some implementations, it means that the compilation unit has been recompiled. In others, it means that the source of the compilation unit has been edited in some significant way.

Note that an implementation cannot require the existence of compilation units upon which the given one does not semantically depend. For example, an implementation is required to be able to compile a compilation unit that says "with A;" when A's body does not exist. It has to be able to detect errors without looking at A's body.

{AI05-0229-1} Similarly, the implementation has to be able to compile a call to a subprogram for which aspects pragma Inline has been specified without seeing the body of that subprogram — inlining would not be achieved in this case, but the call is still legal.

{AI95-00217-06} {AI05-0005-1} The consistencysecond rule applies to limited views as well as the full view of a compilation unit. That means that an implementation needs a way to enforce consistency of limited views, not just of full views.

Implementation Permissions

{AI95-00217-06} The implementation may require that a compilation unit be legal before it can be mentioned in a limited_with_clause or it can be inserted into the environment.

{AI95-00214-01} {AI05-0229-1} When a compilation unit that declares or renames a library unit is added to the environment, the implementation may remove from the environment any preexisting library_item or subunit with the same full expanded name with the same defining_program_unit_name. When a compilation unit that is a subunit or the body of a library unit is added to the environment, the
When a given compilation unit is removed from the environment, the implementation may also remove
any preexisting preexisting version of the same compilation unit.

When a compilation unit that contains a body_stub is added to the environment, the implementation may
remove any preexisting library_item or subunit with the same full expanded name as the body_stub.

When a given compilation unit is removed from the environment, the implementation may also remove
any compilation unit that depends semantically upon the given one. If the given compilation unit contains
the body of a subprogram for which aspect pragma Inline is True, the implementation may also
remove any compilation unit containing a call to that subprogram.

7.a/3

Ramification: \{AI05-0005-1\} The permissions given in this paragraph correspond to the traditional model, where
compilation units enter the environment by being compiled into it, and the compiler checks their legality at that time.

An A implementation model in which the environment consists of all source files in a given directory might not want to
take advantage of these permissions. Compilation units would not be checked for legality as soon as they enter the
environment; legality checking would happen later, when compilation units are compiled. In this model, compilation
units might never be automatically removed from the environment; they would be removed when the user explicitly
deletes a source file.

7.b

Note that the rule is recursive: if the above permission is used to remove a compilation unit containing an inlined subprogram call, then compilation units that depend semantically upon the removed one may also be removed, and so on.

7.c

Note that here we are talking about dependences among existing compilation units in the environment; it doesn't matter
what with_clauses are attached to the new compilation unit that triggered all this.

7.d/3

\{AI05-0229-1\} An implementation may have other modes in which compilation units in addition to the ones
mentioned above are removed. For example, an implementation might inline subprogram calls without an explicit
aspect pragma Inline. If so, it either has to have a mode in which that optimization is turned off, or it has to
automatically regenerate code for the inlined calls without requiring the user to resubmit them to the compiler.

7.d.1/2

Discussion: \{AI95-00077-01\} \{AI95-00114-01\} In the standard mode, implementations may only
remove units from the environment for one of the reasons listed here, or in response to an explicit user command to
modify the environment. It is not intended that the act of compiling a unit is one of the “mechanisms” for
removing units other than those specified by this International Standard.

7.e/2

\{AI95-00214-01\} These rules are intended to ensure that an implementation never need keep more than one
compilation unit with any full expanded name. In particular, it is not necessary to be able to have a subunit and a child
unit with the same name in the environment at one time.

Notes

5 The rules of the language are enforced across compilation and compilation unit boundaries, just as they are enforced
within a single compilation unit.

8.a/3

Ramification: \{AI05-0299-1\} Note that Clause Section 1 requires an implementation to detect illegal compilation units at
compile time.

9

6 An implementation may support a concept of a library, which contains library_items. If multiple libraries are supported,
the implementation has to define how a single environment is constructed when a compilation unit is submitted to the
compiler. Naming conflicts between different libraries might be resolved by treating each library as the root of a hierarchy
of child library units.

9.a

Implementation Note: Alternatively, naming conflicts could be resolved via some sort of hiding rule.

9.b

Discussion: For example, the implementation might support a command to import library Y into library X. If a root
library unit called LU (that is, Standard.LU) exists in Y, then from the point of view of library X, it could be called
Y.LU. X might contain library units that say, “with Y.LU;”.

10

7 A compilation unit containing an instantiation of a separately compiled generic unit does not semantically depend on the
body of the generic unit. Therefore, replacing the generic body in the environment does not result in the removal of the
compilation unit containing the instantiation.

10.a

Implementation Note: Therefore, implementations have to be prepared to automatically instantiate generic bodies at
link-time, as needed. This might imply a complete automatic recompilation, but it is the intent of the language that
generic bodies can be (re)instantiated without forcing all of the compilation units that semantically depend on the
compilation unit containing the instantiation to be recompiled.

Extensions to Ada 83

\{AI95-00077-01\} \{AI95-00114-01\} Ada 83 allowed implementations to require that the body of a generic unit be
available when the instantiation is compiled, that permission is dropped in Ada 95. This isn’t really an extension (it
doesn’t allow Ada users to write anything that they couldn’t in Ada 83), but there isn’t a more appropriate category, and
it does allow users more flexibility when developing programs.
Wording Changes from Ada 95

\{8652/0032\} \{AI95-00192-01\} Corrigendum: The wording was clarified to ensure that a subprogram_body is not considered a completion of an instance of a generic subprogram.

\{AI95-00214-01\} The permissions to remove a unit from the environment were clarified to ensure that it is never necessary to keep multiple (sub)units with the same full expanded name in the environment.

\{AI95-00217-06\} Units mentioned in a limited_with_clause were added to several rules; limited views have the same presence in the environment as the corresponding full views.

10.1.4 Pragmas and Program Units

[This subclause discusses pragmas related to program units, library units, and compilations.]

Name Resolution Rules

Certain pragmas are defined to be program unit pragmas. A name given as the argument of a program unit pragma shall resolve to denote the declarations or renamings of one or more program units that occur immediately within the declarative region or compilation in which the pragma immediately occurs, or it shall resolve to denote the declaration of the immediately enclosing program unit (if any); the pragma applies to the denoted program unit(s). If there are no names given as arguments, the pragma applies to the immediately enclosing program unit.

Ramification: The fact that this is a Name Resolution Rule means that the pragma will not apply to declarations from outer declarative regions.

Legality Rules

A program unit pragma shall appear in one of these places:

- At the place of a compilation_unit, in which case the pragma shall immediately follow in the same compilation (except for other pragmas) a library_unit_declaration that is a subprogram_declaration, generic_subprogram_declaration, or generic_instantiation, and the pragma shall have an argument that is a name denoting that declaration.

  Ramification: The name has to denote the immediately preceding library_unit_declaration.

- \{8652/0033\} \{AI95-00136-01\} Immediately within the visible part declaration of a program unit and before any nested declaration (but not within a generic formal part), in which case the argument, if any, shall be a direct_name that denotes the immediately enclosing program unit declaration.

  Ramification: The argument is optional in this case.

- At the place of a declaration other than the first, of a declarative_part or program unit declaration, in which case the pragma shall have an argument, which shall be a direct_name that denotes one or more of the following (and nothing else): a subprogram_declaration, a generic_subprogram_declaration, or a generic_instantiation, of the same declarative_part or program unit declaration.

  Ramification: If you want to denote a subprogram_body that is not a completion, or a package_declaration, for example, you have to put the pragma inside.

\{AI05-0132-1\} Certain program unit pragmas are defined to be library unit pragmas. If a library unit pragma applies to a program unit, the program unit shall be The name, if any, in a library unit pragma shall denote the declaration of a library unit.

Ramification: This, together with the rules for program unit pragmas above, implies that if a library unit pragma applies to a subprogram_declaration (and similar things), it has to appear immediately after the compilation_unit, whereas if the pragma applies to a package_declaration, a subprogram_body that is not a completion (and similar things), it has to appear inside, as the first declarative_item.
A library unit pragma that applies to a generic unit does not apply to its instances, unless a specific rule for the pragma specifies the contrary.

Certain pragmas are defined to be configuration pragmas; they shall appear before the first compilation_unit of a compilation. [They are generally used to select a partition-wide or system-wide option.] The pragma applies to all compilation_units appearing in the compilation, unless there are none, in which case it applies to all future compilation_units compiled into the same environment.

An implementation may require that configuration pragmas that select partition-wide or system-wide options be compiled place restrictions on configuration pragmas, so long as it allows them when the environment contains no library_items other than those of the predefined environment. In this case, the implementation shall still accept configuration pragmas in individual compilations that confirm the initially selected partition-wide or system-wide options.

When applied to a generic unit, a program unit pragma that is not a library unit pragma should apply to each instance of the generic unit for which there is not an overriding pragma applied directly to the instance.

Corrigendum: The wording was corrected to ensure that a program unit pragma cannot appear in private parts or generic formal parts.

Corrigendum: The wording was clarified to explain the meaning of program unit and library unit pragmas in generic units.

The Implementation Advice added by the Corrigendum was moved, as it was not in the normal order. (This changes the paragraph number.) It originally was directly after the new Static Semantics rule.

The permission to place restrictions was clarified to:

- Ensure that it applies only to partition-wide configuration pragmas, not ones like Assertion_Policy (see 11.4.2), which can be different in different units; and
- Ensure that confirming pragmas are always allowed.

Correction: A library unit pragma must apply directly to a library unit, even if no name is given in the pragma.

[The normal visibility rules do not apply within a parent_unit_name or a context_clause, nor within a pragma that appears at the place of a compilation unit. The special visibility rules for those contexts are given here.]
those that are explicit library_items of the environment, and the only declarations that are directly visible are those that are explicit root library_items of the environment. Within a limited_with_clause, the only declarations that are visible are those that are the implicit declaration of the limited view of a library package of the environment, and the only declarations that are directly visible are those that are the implicit declaration of the limited view of a root library package. Notwithstanding the rules of 4.1.3, an expanded name in a with_clause may consist of a prefix that denotes a generic package and a selector_name that denotes a child of that generic package. ([The child is necessarily a generic unit; see 10.1.1.])

Ramification: In “package P.Q.R is ... end P.Q.R.”, this rule requires P to be a root library unit, and Q to be a library unit (because those are the things that are directly visible and visible). Note that visibility does not apply between the “end” and the “;”.  

Physically nested declarations are not visible at these places.

Although Standard is visible at these places, it is impossible to name it, since it is not directly visible, and it has no parent.

{AI95-00217-06} Only compilation units defining limited views can be mentioned in a limited with_clause, while only compilation units defining full views (that is, the explicit declarations) can be mentioned in a nonlimited with_clause. This resolves the conflict inherent in having two compilation units with the same defining name.

This paragraph was deleted Reason: {AI95-00312-01} The “notwithstanding” part allows “with A.B;” where A is a generic library package and B is one of its (generic) children. This is necessary because it is not normally legal to use an expanded name to reach inside a generic package.

Within a use_clause or pragma that is within a context_clause, each library_item mentioned in a previous with_clause of the same context_clause is visible, and each root library_item so mentioned is directly visible. In addition, within such a use_clause, if a given declaration is visible or directly visible, each declaration that occurs immediately within the given declaration's visible part is also visible. No other declarations are visible or directly visible.

Discussion: Note the word “same”. For example, if a with_clause on a declaration mentions X, this does not make X visible in use_clauses and pragmas that are on the body. The reason for this rule is the one-pass context_clauses Language Design Principle.

Note that the second part of the rule does not mention pragmas.

Within the parent_unit_name of a subunit, library_items are visible as they are in the parent_unit_name of a library_item; in addition, the declaration corresponding to each body_stub in the environment is also visible.

Ramification: For a subprogram without a separate subprogram_declaration, the body_stub itself is the declaration.

Within a pragma that appears at the place of a compilation unit, the immediately preceding library_item and each of its ancestors is visible. The ancestor root library_item is directly visible.

{AI95-00312-01} Notwithstanding the rules of 4.1.3, an expanded name in a with_clause, a pragma in a context_clause, or a pragma that appears at the place of a compilation unit may consist of a prefix that denotes a generic package and a selector_name that denotes a child of that generic package. ([The child is necessarily a generic unit; see 10.1.1.])

Reason: This rule allows with A.B; and pragma Elaborate(A,B); where A is a generic library package and B is one of its (generic) children. This is necessary because it is not normally legal to use an expanded name to reach inside a generic package.

Wording Changes from Ada 83

The special visibility rules that apply within a parent_unit_name or a context_clause, and within a pragma that appears at the place of a compilation_unit are clarified.

Note that a context_clause is not part of any declarative region.

We considered making the visibility rules within parent_unit_names and context_clauses follow from the context of compilation. However, this attempt failed for various reasons. For example, it would require use_clauses in
context_clauses to be within the declarative region of Standard, which sounds suspiciously like a kludge. And we would still need a special rule to prevent seeing things (in our own context_clause) that were with-ed by our parent, etc.

Wording Changes from Ada 95

\{AI95-00217-06\} Added separate visibility rules for limited_with_clauses; the existing rules apply only to nonlimited_with_clauses.

\{AI95-00312-01\} Clarified that the name of a generic child unit may appear in a pragma in a context_clause.

10.2 Program Execution

An Ada program consists of a set of partitions[, which can execute in parallel with one another, possibly in a separate address space, and possibly on a separate computer.]

Post-Compilation Rules

A partition is a program or part of a program that can be invoked from outside the Ada implementation. [For example, on many systems, a partition might be an executable file generated by the system linker.] The user can explicitly assign library units to a partition. The assignment is done in an implementation-defined manner. The compilation units included in a partition are those of the explicitly assigned library units, as well as other compilation units needed by those library units. The compilation units needed by a given compilation unit are determined as follows (unless specified otherwise via an implementation-defined pragma, or by some other implementation-defined means):

Discussion: From a run-time point of view, an Ada 95 partition is identical to an Ada 83 program — implementations were always allowed to provide inter-program communication mechanisms. The additional semantics of partitions is that interfaces between them can be defined to obey normal language rules (as is done in Annex E, “Distributed Systems”), whereas interfaces between separate programs had no particular semantics.

Implementation defined: The manner of explicitly assigning library units to a partition.

Implementation defined: The implementation-defined means, if any, of specifying which compilation units are needed by a given compilation unit.

Discussion: There are no pragmas that “specify otherwise” defined by the core language. However, an implementation is allowed to provide such pragmas, and in fact Annex E, “Distributed Systems” defines some pragmas whose semantics includes reducing the set of compilation units described here.

• A compilation unit needs itself;
• If a compilation unit is needed, then so are any compilation units upon which it depends semantically;
• If a library_unit_declaration is needed, then so is any corresponding library_unit_body;
• \{AI95-00217-06\} If a compilation unit with stubs is needed, then so are any corresponding subunits;

Discussion: Note that in the environment, the stubs are replaced with the corresponding proper_bodies.

• \{AI95-00217-06\} If the (implicit) declaration of the limited view of a library package is needed, then so is the explicit declaration of the library package.

Discussion: Note that a child unit is not included just because its parent is included — to include a child, mention it in a with_clause.

• \{AI95-00217-06\} A package is included in a partition even if the only reference to it is in a limited_with_clause. While this isn't strictly necessary (no objects of types imported from such a unit can be created), it ensures that all incomplete types are eventually completed, and is the least surprising option.

The user can optionally designate (in an implementation-defined manner) one subprogram as the main subprogram for the partition. A main subprogram, if specified, shall be a subprogram.
Discussion: This may seem superfluous, since it follows from the definition. But we would like to have every error message that might be generated (before run time) by an implementation correspond to some explicitly stated “shall” rule.

Of course, this does not mean that the “shall” rules correspond one-to-one with an implementation’s error messages. For example, the rule that says overload resolution “shall” succeed in producing a single interpretation would correspond to many error messages in a good implementation — the implementation would want to explain to the user exactly why overload resolution failed. This is especially true for the syntax rules — they are considered part of overload resolution, but in most cases, one would expect an error message based on the particular syntax rule that was violated.

Implementation defined: The manner of designating the main subprogram of a partition.

Ramification: An implementation cannot require the user to specify, say, all of the library units to be included. It has to support, for example, perhaps the most typical case, where the user specifies just one library unit, the main program. The implementation has to do the work of tracking down all the other ones.

Each partition has an anonymous environment task[, which is an implicit outermost task whose execution elaborates the library items of the environment declarative part, and then calls the main subprogram, if there is one. A partition’s execution is that of its tasks.]

Ramification: An environment task has no master; all nonenvironment tasks have masters.

An implementation is allowed to support multiple concurrent executions of the same partition.

[The order of elaboration of library units is determined primarily by the elaboration dependences.] There is an elaboration dependence of a given library_item upon another if the given library_item or any of its subunits depends semantically on the other library_item. In addition, if a given library_item or any of its subunits has a pragma Elaborate or Elaborate_All that names another library unit, then there is an elaboration dependence of the given library_item upon the body of the other library unit, and, for Elaborate_All only, upon each library_item needed by the declaration of the other library unit.

Discussion: “Mentions” was introduced informally in the above rule; it was not intended to refer to the definition of mentions in 10.1.2. It was changed to “names” to make this clear. It would have been better to use “names” instead of “mentions” above.

See above for a definition of which library_items are “needed by” a given declaration.

Note that elaboration dependences are among library_items, whereas the other two forms of dependence are among compilation units. Note that elaboration dependence includes semantic dependence. It’s a little bit sad that pragma Elaborate_Body can’t be folded into this mechanism. It follows from the definition that the elaboration dependence relationship is transitive. Note that the wording of the rule does not need to take into account a semantic dependence of a library_body or one of its subunits upon a subunit of a different library unit, because that can never happen.

The environment task for a partition has the following structure:

```ada
task Environment_Task;

task body Environment_Task is
    ... (1) -- The environment declarative_part
    ... (2) -- Call the main subprogram, if there is one.
end Environment_Task;
```

Ramification: The name of the environment task is written in italics here to indicate that this task is anonymous.

Discussion: The model is different for a “passive partition” (see E.1). Either there is no environment task, or its sequence_of_statements is an infinite loop rather than a call on a main subprogram.

The environment declarative_part at (1) is a sequence of declarative_items consisting of copies of the library_items included in the partition[]. The order of elaboration of library_items is the order in which they appear in the environment declarative_part:

- The order of all included library_items is such that there are no forward elaboration dependences.

Ramification: This rule is written so that if a library_item depends on itself, we don't require it to be elaborated before itself. See A183-00113/12. This can happen only in pathological circumstances. For example, if a library subprogram_body has no corresponding subprogram_declaration, and one of the subunits of the subprogram_body mentions the subprogram_body in a with_clause, the subprogram_body will depend on itself. For another example, if
a library_unit_body applies a pragma Elaborate_All to its own declaration, then the library_unit_body will depend on itself.

- \{AI05-0229-1\} Any included library_unit_declaration for which aspect pragma Elaborate_Body is True \[(including when a pragma Elaborate_Body applies)\] applies is immediately followed by its library_unit_body, if included.

**Discussion:** This implies that the body of such a library unit shall not “with” any of its own children, or anything else that depends semantically upon the declaration of the library unit.

**Proof:** \{AI05-0229-1\} Pragma Elaborate_Body sets aspect Elaborate_Body, see 10.2.1.

- All library_items declared pure occur before any that are not declared pure.
- All preelaborated library_items occur before any that are not preelaborated.

**Discussion:** Normally, if two partitions contain the same compilation unit, they each contain a separate copy of that compilation unit. See Annex E, “Distributed Systems” for cases where two partitions share the same copy of something.

There is no requirement that the main subprogram be elaborated last. In fact, it is possible to write a partition in which the main subprogram cannot be elaborated last.

**Ramification:** This declarative_part has the properties required of all environments (see 10.1.4). However, the environment declarative_part of a partition will typically contain fewer compilation units than the environment declarative_part used at compile time — only the “needed” ones are included in the partition.

There shall be a total order of the library_items that obeys the above rules. The order is otherwise implementation defined.

**Discussion:** The only way to violate this rule is to have Elaborate, Elaborate_All, or Elaborate_Body pragmas that cause circular ordering requirements, thus preventing an order that has no forward elaboration dependences.

**Implementation defined:** The order of elaboration of library_items.

**To be honest:** Notwithstanding what the RM95 says elsewhere, each rule that requires a declaration to have a corresponding completion is considered to be a Post-Compilation Rule when the declaration is that of a library unit.

**Discussion:** Such rules may be checked at “link time,” for example. Rules requiring the completion to have certain properties, on the other hand, are checked at compile time of the completion.

The full expanded names of the library units and subunits included in a given partition shall be distinct.

**Reason:** This is a Post-Compilation Rule because making it a Legality Rule would violate the Language Design Principle labeled “legality determinable via semantic dependences.”

The sequence_of_statements of the environment task (see 2 above) consists of either:

- A call to the main subprogram, if the partition has one. If the main subprogram has parameters, they are passed; where the actuals come from is implementation defined. What happens to the result of a main function is also implementation defined.

  **Implementation defined:** Parameter passing and function return for the main subprogram.

  or:

- A null_statement, if there is no main subprogram.

  **Discussion:** For a passive partition, either there is no environment task, or its sequence_of_statements is an infinite loop. See E.1.

The mechanisms for building and running partitions are implementation defined. [These might be combined into one operation, as, for example, in dynamic linking, or “load-and-go” systems.]

**Implementation defined:** The mechanisms for building and running partitions.

Dynamic Semantics

The execution of a program consists of the execution of a set of partitions. Further details are implementation defined. The execution of a partition starts with the execution of its environment task, ends when the environment task terminates, and includes the executions of all tasks of the partition. [The
execution of the (implicit) task_body of the environment task acts as a master for all other tasks created as part of the execution of the partition. When the environment task completes (normally or abnormally), it waits for the termination of all such tasks, and then finalizes any remaining objects of the partition.]

**Ramification:** The “further details” mentioned above include, for example, program termination — it is implementation defined. There is no need to define it here; it’s entirely up to the implementation whether it wants to consider the program as a whole to exist beyond the existence of individual partitions.

**Implementation defined:** The details of program execution, including program termination.

**To be honest:** The execution of the partition terminates (normally or abnormally) when the environment task terminates (normally or abnormally, respectively).

### Bounded (Run-Time) Errors

Once the environment task has awaited the termination of all other tasks of the partition, any further attempt to create a task (during finalization) is a bounded error, and may result in the raising of Program_Error either upon creation or activation of the task. If such a task is activated, it is not specified whether the task is awaited prior to termination of the environment task.

### Implementation Requirements

The implementation shall ensure that all compilation units included in a partition are consistent with one another, and are legal according to the rules of the language.

**Discussion:** The consistency requirement implies that a partition cannot contain two versions of the same compilation unit. That is, a partition cannot contain two different library units with the same full expanded name, nor two different bodies for the same program unit. For example, suppose we compile the following:

```ada
package A is -- Version 1.
...
end A;

with A;
package B is
package A is -- Version 2.
...
end A;

with A;
package C is
end C;
```

It would be wrong for a partition containing B and C to contain both versions of A. Typically, the implementation would require the use of Version 2 of A, which might require the reccompilation of B. Alternatively, the implementation might automatically recompile B when the partition is built. A third alternative would be an incremental compiler that, when Version 2 of A is compiled, automatically patches the object code for B to reflect the changes to A (if there are any relevant changes — there might not be any).

An implementation that supported fancy version management might allow the use of Version 1 in some circumstances. In no case can the implementation allow the use of both versions in the same partition (unless, of course, it can prove that the two versions are semantically identical).

The core language says nothing about inter-partition consistency; see also Annex E, “Distributed Systems”.

### Implementation Permissions

{AI05-0299-1} The kind of partition described in this subclause is known as an active partition. An implementation is allowed to support other kinds of partitions, with implementation-defined semantics.

**Implementation defined:** The semantics of any nonactive partitions supported by the implementation.

**Discussion:** Annex E, “Distributed Systems” defines the concept of passive partitions; they may be thought of as a partition without an environment task, or as one with a particularly simple form of environment task, having an infinite loop rather than a call on a main subprogram as its sequence_of_statements.

An implementation may restrict the kinds of subprograms it supports as main subprograms. However, an implementation is required to support all main subprograms that are public parameterless library procedures.
10.2 Program Execution

Ramification: The implementation is required to support main subprograms that are procedures declared by generic_instantiations, as well as those that are children of library units other than Standard. Generic units are, of course, not allowed to be main subprograms, since they are not subprograms.

Note that renamings are irrelevant to this rule. This rules says which subprograms (not views) have to be supported. The implementation can choose any way it wants for the user to indicate which subprogram should be the main subprogram. An implementation might allow any name of any view, including those declared by renamings. Another implementation might require it to be the original name. Another implementation still might use the name of the source file or some such thing.

If the environment task completes abnormally, the implementation may abort any dependent tasks.

Reason: If the implementation does not take advantage of this permission, the normal action takes place — the environment task awaits those tasks.

The possibility of aborting them is not shown in the environment_task code above, because there is nowhere to put an exception_handler that can handle exceptions raised in both the environment_declarative_part and the main subprogram, such that the dependent tasks can be aborted. If we put an exception_handler in the body of the environment task, then it won't handle exceptions that occur during elaboration of the environment_declarative_part. If we were to move those things into a nested block_statement, with the exception_handler outside that, then the block_statement would await the library tasks we are trying to abort.

Furthermore, this is merely a permission, and is not fundamental to the model, so it is probably better to state it separately anyway.

Note that implementations (and tools like debuggers) can have modes that provide other behaviors in addition.

NOTES

8 An implementation may provide inter-partition communication mechanism(s) via special packages and pragmas. Standard pragmas for distribution and methods for specifying inter-partition communication are defined in Annex E, “Distributed Systems”. If no such mechanisms are provided, then each partition is isolated from all others, and behaves as a program in and of itself.

Ramification: Not providing such mechanisms is equivalent to disallowing multi-partition programs.

9 Partitions are not required to run in separate address spaces. For example, an implementation might support dynamic linking via the partition concept.

10 An order of elaboration of library_items that is consistent with the partial ordering defined above does not always ensure that each library_unit_body is elaborated before any other compilation unit whose elaboration necessitates that the library_unit_body be already elaborated. (In particular, there is no requirement that the body of a library unit be elaborated as soon as possible after the library_unit_declaration is elaborated, unless the pragmas in subclause 10.2.1 are used.)

11 A partition (active or otherwise) need not have a main subprogram. In such a case, all the work done by the partition would be done by elaboration of various library_items, and by tasks created by that elaboration. Passive partitions, which cannot have main subprograms, are defined in Annex E, “Distributed Systems”.

Ramification: The environment task is the outermost semantic level defined by the language.

Standard has no private part. This prevents strange implementation-dependences involving private children of Standard having visibility upon Standard's private part. It doesn't matter where the body of Standard appears in the environment, since it doesn't do anything. See Annex A, “Predefined Language Environment”.

Note that elaboration dependence is carefully defined in such a way that if (say) the body of something doesn't exist yet, then there is no elaboration dependence upon the nonexistent body. (This follows from the fact that "needed by" is defined that way, and the elaboration dependences caused by a pragma Elaborate or Elaborate_All are defined in terms of "needed by"). This property allows us to use the environment concept both at compile time and at partition-construction time/run time.

.Extensions to Ada 83

The concept of partitions is new to Ada 95.

A main subprogram is now optional. The language-defined restrictions on main subprograms are relaxed.

Wording Changes from Ada 83

Ada 95 uses the term “main subprogram” instead of Ada 83’s “main program” (which was inherited from Pascal). This is done to avoid confusion — a main subprogram is a subprogram, not a program. The program as a whole is an entirely different thing.
10.2 Wording Changes from Ada 95

{AI95-00256-01} The mistaken use of “mentions” in the elaboration dependence rule was fixed.

{AI95-00217-06} The needs relationship was extended to include limited views.

10.2.1 Elaboration Control

[This subclause defines pragmas that help control the elaboration order of library_items.]

Language Design Principles

The rules governing preelaboration are designed to allow it to be done largely by bulk initialization of statically allocated storage from information in a “load module” created by a linker. Some implementations may require run-time code to be executed in some cases, but we consider these cases rare enough that we need not further complicate the rules.

It is important that programs be able to declare data structures that are link-time initialized with aggregates, string_literals, and concatenations thereof. It is important to be able to write link-time evaluated expressions involving the First, Last, and Length attributes of such data structures (including variables), because they might be initialized with positional aggregates or string_literals, and we don’t want the user to have to count the elements. There is no corresponding need for accessing discriminants, since they can be initialized with a static constant, and then the constant can be referred to elsewhere. It is important to allow link-time initialized data structures involving discriminant-dependent components. It is important to be able to write link-time evaluated expressions involving pointers (both access values and addresses) to the above-mentioned data structures.

The rules also ensure that no Elaboration_Check need be performed for calls on library-level subprograms declared within a preelaborated package. This is true also of the Elaboration_Check on task activation for library level task types declared in a preelaborated package. However, it is not true of the Elaboration_Check on instantiations.

A static expression should never prevent a library unit from being preelaborable.

Syntax

The form of a pragma Preelaborate is as follows:

```ada
pragma Preelaborate((library_unit_name));
```

A pragma Preelaborate is a library unit pragma.

{AI95-00161-01} The form of a pragma Preelaborable_Initialization is as follows:

```ada
pragma Preelaborable_Initialization(direct_name);
```

Legality Rules

An elaborable construct is preelaborable unless its elaboration performs any of the following actions:

**Ramification:** A preelaborable construct can be elaborated without using any information that is available only at run time. Note that we don’t try to prevent exceptions in preelaborable constructs; if the implementation wishes to generate code to raise an exception, that’s OK.

Because there is no flow of control and there are no calls (other than to predefined subprograms), these run-time properties can actually be detected at compile time. This is necessary in order to require compile-time enforcement of the rules.

- The execution of a statement other than a null_statement.
- A call to a subprogram other than a static function.
- The evaluation of a primary that is a name of an object, unless the name is a static expression, or statically denotes a discriminant of an enclosing type.

**Ramification:** One can evaluate such a name, but not as a primary. For example, one can evaluate an attribute of the object. One can evaluate an attribute_reference, so long as it does not denote an object, and its prefix does not disobey any of these rules. For example, Obj’Access, Obj’Unchecked_Access, and Obj’Address are generally legal in preelaborated library units.
The creation of an object [(including a component)] that is initialized by default, if itself a type that does not have preelaborable initialization. Similarly a default-initialized object [(including a component)] of a descendant of a private type, private extension, controlled type, task type, or protected type with entry declaration, similarly the evaluation of an extension_aggregate with an ancestor subtype_mark denoting a subtype of such a type.

Ramification: One can declare these kinds of types, but one cannot create objects of those types.

It is also nonpreelaborable to create an object if that will cause the evaluation of a default expression that will call a user-defined function. This follows from the rule above forbidding nonnull statements.

This paragraph was deleted. Reason: Controlled objects are disallowed because most implementations will have to take some run time action during initialization, even if the Initialize procedure is null.

A generic body is preelaborable only if elaboration of a corresponding instance body would not perform any such actions, presuming that: the actual for each formal private type (or extension) is a private type (or extension), and the actual for each formal subprogram is a user-defined subprogram.

The actual for each formal type is nonstatic; and

the actual for each formal object is nonstatic; and

the actual for each formal subprogram is a user-defined subprogram.

Discussion: This is an “assume-the-worst” rule. The elaboration of a generic unit doesn't perform any of the actions listed above, because its sole effect is to establish that the generic can from now on be instantiated. So the elaboration of the generic itself is not the interesting part when it comes to preelaboration rules. The interesting part is what happens when you elaborate “any instantiation” of the generic. For instance, declaring an object of a limited formal private type might well start tasks, call functions, and do all sorts of nonpreelaborable things. We prevent these situations by assuming that the actual parameters are as badly behaved as possible.

Reason: Without this rule about generics, we would have to forbid instantiations in preelaborated library units, which would significantly reduce their usefulness.

A pragma Preelaborate (or pragma Pure — see below) is used to specify that applies to a library unit, then it is preelaborated, namely that the Preelaborate aspect of the library unit is True; all compilation units of the library unit are preelaborated.

If a library unit is preelaborated, then its declaration, if any, and body, if any, are elaborated prior to all nonpreelaborated library_items of the partition.

The declaration and body of a preelaborated library unit, and all subunits that are elaborated as part of elaborating the library unit, all compilation units of a preelaborated library unit shall be preelaborated. All compilation units of a preelaborated library unit shall depend semantically only on declared pure or preelaborated library_items. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply this rule applies also in the private part of an instance of a generic unit.

In a generic body, we assume the worst about formal private types and extensions.

Subunits of a preelaborated subprogram unit do not need to be preelaborable. This is needed in order to be consistent with units nested in a subprogram body, which do not need to be preelaborable even if the subprogram is preelaborated. However, such subunits cannot depend semantically on nonpreelaborated units, which is also consistent with nested units.

Aspect Description for Preelaborate: Code execution during elaboration is avoided for a given package.

The following rules specify which entities have preelaborable initialization:
• \{AI05-0028-1\} The partial view of a private type or private extension, a protected type without entry declarations, a generic formal private type, or a generic formal derived type, have preelaborable initialization if and only if the pragma Preelaborable Initialization has been applied to them. [A protected type with entry declarations or a task type never has preelaborable initialization.]

• A component (including a discriminant) of a record or protected type has preelaborable initialization if its declaration includes a default expression whose execution does not perform any actions prohibited in preelaborable constructs as described above, or if its declaration does not include a default expression and its type has preelaborable initialization.

• \{AI05-0028-1\} \{AI05-0221-1\} A derived type has preelaborable initialization if its parent type has preelaborable initialization and (in the case of a derived record extension) if the noninherited components all have preelaborable initialization. However, a user-defined controlled type with an overriding Initialize procedure that is not a null procedure does not have preelaborable initialization.

• \{AI95-00161-01\} \{AI95-00345-01\} A view of a type has preelaborable initialization if it is an elementary type, an array type whose component type has preelaborable initialization, a record type whose components all have preelaborable initialization, or an interface type.

\{AI95-00161-01\} A pragma Preelaborable Initialization specifies that a type has preelaborable initialization. This pragma shall appear in the visible part of a package or generic package.

\{AI95-00161-01\} \{AI95-00345-01\} \{AI05-0028-1\} If the pragma appears in the first list of basic declarative items of a package specification, then the direct_name shall denote the first subtype of a composite private type, private extension, or protected type that is not an interface type and is without entry declarations, and the type shall be declared immediately within the same package as the pragma. If the pragma is applied to a private type or a private extension, the full view of the type shall have preelaborable initialization. If the pragma is applied to a protected type, the protected type shall not have entries, and each component of the protected type shall have preelaborable initialization. For any other composite type, the type shall have preelaborable initialization. In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

**Reason:** \{AI05-0028-1\} The reason why we need the pragma for private types, private extensions, and protected types is fairly clear: the properties of the full view determine whether the type has preelaborable initialization or not; in order to preserve privacy we need a way to express on the partial view that the full view is well-behaved. The reason why we need the pragma for other composite types is more subtle: a nonnull override for Initialize might occur in the private part, even for a nonprivate type; in order to preserve privacy, we need a way to express on a type declared in a visible part that the private part does not contain any nasty override of Initialize.

\{AI95-00161-01\} If the pragma appears in a generic formal part, then the direct_name shall denote a generic formal private type or a generic formal derived type declared in the same generic formal part as the pragma. In a generic instantiation the corresponding actual type shall have preelaborable initialization.

**Ramification:** Not only do protected types with entry declarations and task types not have preelaborable initialization, but they cannot have pragma Preelaborable Initialization applied to them.

**Implementation Advice**

In an implementation, a type declared in a preelaborated package should have the same representation in every elaboration of a given version of the package, whether the elaborations occur in distinct executions of the same program, or in executions of distinct programs or partitions that include the given version.

**Implementation Advice:** A type declared in a preelaborated package should have the same representation in every elaboration of a given version of the package.
The form of a pragma Pure is as follows:

```
pragma Pure(library_unit_name);
```

A pragma Pure is a library unit pragma.

**Syntax**

**Static Semantics**

- A pure compilation unit/library_item is a preelaborable compilation unit/library_item whose elaboration does not perform any of the following actions:
  - the elaboration of a variable declaration;
  - the evaluation of an allocator of an access-to-variable type; for the purposes of this rule, the partial view of a type is presumed to have nonvisible components whose default initialization evaluates such an allocator;
  - the elaboration of the declaration of a nonderived named access-to-variable type unless the Storage_Size of the type has been specified by a static expression with value zero or is defined by the language to be zero;
  - the elaboration of the declaration of a nonderived named access-to-constant type for which the Storage_Size has been specified by an expression other than a static expression with value zero;
  - the elaboration of the declaration of a nonderived named access-to-constant type for which the Storage_Size has been specified by an expression other than a static expression with value zero.

- A generic body is pure only if elaboration of a corresponding instance body would not perform any such actions presuming any composite formal types have nonvisible components whose default initialization evaluates an allocator of an access-to-variable type.

- The Storage_Size for an anonymous access-to-variable type declared at library level in a library unit that is declared pure is defined to be zero.

**Ramification:** This makes allocators illegal for such types (see 4.8), making a storage pool unnecessary for these types. A storage pool would represent state.

- Note that access discriminants and access parameters are never library-level, even when they are declared in a type or subprogram declared at library-level. That’s because they have their own special accessibility rules (see 3.10.2).
Legality Rules

This paragraph was deleted. {AI95-00366-01} A pure library_item is a preelaborable library_item that does not contain the declaration of any variable or named access within a subprogram, generic subprogram, task unit, or protected unit.

{AI95-00366-01} {AI05-0034-1} {AI05-0035-1} {AI05-0243-1} A pragma Pure is used to specify declare that a library unit is declared pure, namely that the Pure aspect of the library unit is True; all compilation units of the library unit are declared pure. In addition, the limited view of any library package is declared pure. The declaration and body of a declared pure library unit, and all subunits that are elaborated as part of elaborating the library unit, shall be pure. All if a pragma Pure applies to a library unit, then its compilation units of a declared pure library unit shall be pure, and they shall depend semantically only on compilation units of other library units that are declared pure library_items. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. Furthermore, the full view of any partial view declared in the visible part of a declared pure the library unit that has any available stream attributes shall support external streaming (see 13.13.2).

Discussion: A declared-pure package is useful for defining types to be shared between partitions with no common address space.

Reason: Note that generic packages are not mentioned in the list of things that can contain variable declarations. Note that the Ada 95 rules for deferred constants make them allowable in library units that are declared pure; that isn't true of Ada 83's deferred constants.

Ramification: {AI95-00366-01} Anonymous access types (that is, access discriminants and access parameters) are allowed.

{AI05-0243-1} A limited view is not a library unit, so any rule that starts “declared pure library unit” does not apply to a limited view. In particular, the 3rd and last sentences never apply to limited views. However, a limited view is a library_item, so rules that discuss “declared pure library_items” do include limited views.

Reason: {AI95-00366-01} Ada 95 didn't allow any access types as The primary reason for disallowing named access types is that an allocator has a side effect; the pool constitutes variable data. We considered somehow allowing allocator less access types. However, these (including access-to-subprogram types) would cause trouble for Annex E, “Distributed Systems”, because such types would allow access values in a shared passive partition to designate objects in an active partition, thus allowing inter-address space references. We decided to disallow such uses in the relatively rare cases where they cause problems, rather than making life harder for the majority of users. Types declared in a pure package can be used in remote operations only if they are externally streamable. That simply means that there is a means to transport values of the type; that's automatically true for nonlimited types that don't have an access part. The only tricky part about this is to avoid privacy leakage; that was handled by ensuring that any private types (and private extensions) declared in a pure package that have available stream attributes (which include all nonlimited types by definition) have to be externally streamable Furthermore, a named access-to-object type without a pool would be a new concept, adding complexity from the user's point of view. Finally, the prevention of allocators would have to be a run-time check, in order to avoid violations of the generic contract model.

Aspect Description for Pure: Side effects are avoided in the subprograms of a given package.

Implementation Permissions

{AI95-00366-01} {AI05-0219-1} If a library unit is declared pure, then the implementation is permitted to omit a call on a library-level subprogram of the library unit if the results are not needed after the call. In addition, the implementation Similarly, it may omit such a call on such a subprogram and simply reuse the results produced by an earlier call on the same subprogram, provided that none of the parameters nor any object accessible via access values from the parameters have any part that is of a type whose full type is an immutably core of a limited type, and the addresses and values of all by-reference actual parameters, and the values of all by-copy-in actual parameters, and the values of all objects accessible via access values from the parameters, are the same as they were at the earlier call. [This permission applies even if the subprogram produces other side effects when called.]
The form of a pragma Elaborate, Elaborate_All, or Elaborate_Body is as follows:

\[
\begin{align*}
\text{pragma Elaborate}(\text{library unit name}, \text{library unit name}) ; \\
\text{pragma Elaborate>All}(\text{library unit name}, \text{library unit name}) ; \\
\text{pragma Elaborate_Body}(\text{library unit name}) ;
\end{align*}
\]

A pragma Elaborate or Elaborate_All is only allowed within a context_clause.

**Discussion:** Hence, a pragma Elaborate or Elaborate_All is not elaborated, not that it makes any practical difference.

Note that a pragma Elaborate or Elaborate_All is neither a program unit pragma, nor a library unit pragma.

**Legality Rules**

\[\{A105-0229-1\} \text{ If the aspects pragma Elaborate_Body is True for } \text{applies to a declaration } [(\text{including when pragma Elaborate_Body applies})], \text{ then the declaration requires a completion } [(\text{a body})].\]

**Proof:** \[A105-0229-1\] Pragma Elaborate_Body sets the aspect (see below).

\[\{A195-00217-06\} \text{ The library unit name of a pragma Elaborate or Elaborate_All shall denote a nonlimited view of a library unit.}\]

**Reason:** These pragmas are intended to prevent elaboration check failures. But a limited view does not make anything visible that has an elaboration check, so the pragmas cannot do anything useful. Moreover, the pragmas would probably reintroduce the circularity that the limited_with_clause was intended to break. So we make such uses illegal.

**Static Semantics**

\[\{A105-0229-1\} \text{ A pragma Elaborate specifies that the body of the named library unit is elaborated before the current library_item. A pragma Elaborate_All specifies that each library_item that is needed by the named library unit declaration is elaborated before the current library_item. A pragma Elaborate_Body specifies that the body of the library unit is elaborated immediately after its declaration.}\]

**Proof:** The official statement of the semantics of these pragmas is given in 10.2.

\[\{A105-0229-1\} \text{ A pragma Elaborate_Body sets the Elaborate_Body representation aspect of the library unit to which it applies to the value True. If the Elaborate_Body aspect of a library unit is True, the body of the library unit is elaborated immediately after its declaration.}\]

**Proof:** The official statement of the semantics of this aspect is given in 10.2.

**Implementation Note:** The presence of a pragma Elaborate_Body simplifies the removal of unnecessary Elaboration_Checks. For a subprogram declared immediately within a library unit to which a pragma Elaborate_Body applies, the only calls that can fail the Elaboration_Check are those that occur in the library unit itself, between the declaration and body of the called subprogram; if there are no such calls (which can easily be detected at compile time if there are no stubs), then no Elaboration_Checks are needed for that subprogram. The same is true for Elaboration_Checks on task activations and instantiations, and for library subprograms and generic units.

**Ramification:** The fact that the unit of elaboration is the library_item means that if a subprogram_body is not a completion, it is impossible for any library_item to be elaborated between the declaration and the body of such a subprogram. Therefore, it is impossible for a call to such a subprogram to fail its Elaboration_Check.
Discussion: The visibility rules imply that each library_unit_name of a pragma Elaborate or Elaborate_All has to denote a library unit mentioned by a previous with_clause of the same context_clause.

Aspect Description for Elaborate_Body: A given package must have a body, and that body is elaborated immediately after the declaration.

NOTES
12 A preelaborated library unit is allowed to have nonpreelaborable children.

Ramification: {8652/0035} [AI95-00002-01] But generally not nonpreelabored subunits. (Nonpreelaborated subunits of subprograms are allowed as discussed above.)

13 A library unit that is declared pure is allowed to have impure children.

Ramification: {8652/0035} [AI95-00002-01] But generally not impure subunits. (Impure subunits of subprograms are allowed as discussed above.)

Ramification:Pragma Elaborate is mainly for closely related library units, such as when two package bodies 'with' each other's declarations. In such cases, Elaborate_All sometimes won't work.

Extensions to Ada 83
The concepts of preelaborability and purity are new to Ada 95. The Elaborate_All, Elaborate_Body, Preelaborate, and Pure pragmas are new to Ada 95.

Pragma Elaborate are allowed to be mixed in with the other things in the context_clause — in Ada 83, they were required to appear last.

Incompatibilities With Ada 95
{AI95-00366-01} The requirement that a partial view with available stream attributes be externally streamable can cause an incompatibility in rare cases. If there is a limited tagged type declared in a pure package with available attributes, and that type is used to declare a private extension in another pure package, and the full type for the private extension has a component of an explicitly limited record type, a protected type, or a type with access discriminants, then the stream attributes will have to be user-specified in the visible part of the package. That is not a requirement for Ada 95, but this combination seems very unlikely in pure packages. Note that this cannot be an incompatibility for a nonlimited type, as all of the types that are allowed in Ada 95 that would require explicitly defined stream attributes are limited (and thus cannot be used as components in a nonlimited type).

{AI95-00403-01} Amendment Correction: Added wording to cover missing cases for preelaborated generic units. This is incompatible as a preelaborated unit could have used a formal object to initialize a library-level object; that isn't allowed in Ada 2005. But such a unit wouldn't really be preelaborable, and Ada 95 compilers can reject such units (as this is a Binding Interpretation), so such units should be very rare.

Extensions to Ada 95
{AI95-00161-01} Amendment Correction: The concept of preelaborable initialization and pragma Preelaborable_Initialization are new. These allow more types of objects to be created in preelaborable units, and fix holes in the old rules.

{AI95-00366-01} Access-to-subprogram types and access-to-object types with a Storage_Size of 0 are allowed in pure units. The permission to omit calls was adjusted accordingly (which also fixes a hole in Ada 95, as access parameters are allowed, and changes in the values accessed by them must be taken into account).

Wording Changes from Ada 95
{AI95-00002-01} Corrigendum: The wording was changed so that subunits of a preelaborated subprogram are also preelaborated.

{AI95-00217-06} Disallowed pragma Elaborate and Elaborate_All for packages that are mentioned in a limited_with_clause.

Incompatibilities With Ada 2005
{AI05-0028-1} Correction: Corrected a serious unintended incompatibility with Ada 95 in the new preelaboration wording — explicit initialization of objects of types that don't have preelaborable initialization was not allowed. Ada 2012 switches back to the Ada 95 rule in these cases. This is unlikely to occur in practice, as it is unlikely that a compiler would have implemented the more restrictive rule (it would fail many ACATS tests if it did).

{AI05-0035-1} Correction: Added an assume-the-worst rule for generic bodies (else they would never be checked for purity) and added the boilerplate so that the entire generic specification is rechecked. Also fixed wording to have consistent handling for subunits for Pure and Preelaborate. An Ada 95 program could have depended on marking a...
generic pure that was not really pure, although this would defeat the purpose of the categorization and likely cause problems with distributed programs.

Extensions to Ada 2005

\{AI05-0035-1\} **Correction:** Adjusted wording so that a subunit can be pure (it is not a library item, but it is a compilation unit).

\{AI05-0035-1\} **Correction:** Adjusted wording so that the rules for access types only apply to nonderived types (derived types share their storage pool with their parent, so if the parent access type is legal, so is any derived type.)

\{AI05-0229-1\} **Correction:** Adjusted wording so that the rules for access types only apply to nonderived types (derived types share their storage pool with their parent, so if the parent access type is legal, so is any derived type.)

\{AI05-0229-1\} **Correction:** Elaborate_Body is now an aspect, so it can be specified by an aspect specification — although the pragma is still preferred by the Standard.

\{AI05-0243-1\} **Correction:** Pure and Preelaborate are now aspects, so they can be specified by an aspect specification — although the pragmas are still preferred by the Standard.

Wording Changes from Ada 2005

\{AI05-0034-1\} **Correction:** Added wording so that a limited view is always treated as pure, no matter what categorization is used for the originating unit. This was undefined in Ada 2005.

\{AI05-0028-1\} **Correction:** Fixed minor issues with preelaborable initialization (PI): null Initialize procedures do not make a type non-PI; formal types with pragma PI can be assumed to have PI; formal extensions are assumed to not have PI; all composite types can have pragma PI (so that the possibility of hidden Initialize routines can be handled); added discriminants of a derived type are not considered in calculating PI.

\{AI05-0219-1\} **Correction:** Clarified that the implementation permission to omit pure subprogram calls does not apply if any part of the parameters or any designated object has a part that is immutably limited. The old wording just said "limited type", which can change via visibility and thus isn't appropriate for dynamic semantics permissions.
11 Exceptions

{AI05-0299-1} [This clause defines the facilities for dealing with errors or other exceptional situations that arise during program execution.] An exception represents a kind of exceptional situation; an occurrence of such a situation (at run time) is called an exception occurrence. [To raise an exception is to abandon normal program execution so as to draw attention to the fact that the corresponding situation has arisen. Performing some actions in response to the arising of an exception is called handling the exception.]

To be honest: ...or handling the exception occurrence.

Ramification: For example, an exception End_Error might represent error situations in which an attempt is made to read beyond end-of-file. During the execution of a partition, there might be numerous occurrences of this exception.

To be honest: When the meaning is clear from the context, we sometimes use “occurrence” as a short-hand for “exception occurrence.”

{AI05-0043-1} {AI05-0258-1} [An exception_declaration declares a name for an exception. An exception can be raised explicitly (for example, initially either by a raise_statement) or implicitly (for example, by the failure of a language-defined check). When an exception arises, control can be transferred to a user-provided exception_handler at the end of a handled_sequence_of_statements, or it can be propagated to a dynamically enclosing execution.]

11.1 Exception Declarations

An exception_declaration declares a name for an exception.

Syntax

{AI05-0183-1} exception_declaration ::= defining_identifier_list : exception [aspect_specification];

Static Semantics

Each single exception_declaration declares a name for a different exception. If a generic unit includes an exception_declaration, the exception_declarations implicitly generated by different instantiations of the generic unit refer to distinct exceptions (but all have the same defining_identifier). The particular exception denoted by an exception name is determined at compilation time and is the same regardless of how many times the exception_declaration is elaborated.

Reason: We considered removing this requirement inside generic bodies, because it is an implementation burden for implementations that wish to share code among several instances. In the end, it was decided that it would introduce too much implementation dependence.

Ramification: Hence, if an exception_declaration occurs in a recursive subprogram, the exception name denotes the same exception for all invocations of the recursive subprogram. The reason for this rule is that we allow an exception occurrence to propagate out of its declaration's innermost containing master; if exceptions were created by their
declarations like other entities, they would presumably be destroyed upon leaving the master; we would have to do something special to prevent them from propagating to places where they no longer exist.

Ramiﬁcation: Exception identities are unique across all partitions of a program.

The predeﬁned exceptions are the ones declared in the declaration of package Standard: Constraint_Error, Program_Error, Storage_Error, and Tasking_Error[; one of them is raised when a language-deﬁned check fails.]

Ramiﬁcation: The exceptions declared in the language-deﬁned package IO Exceptions, for example, are not predeﬁned.

Dynamic Semantics

The elaboration of an exception_declaration has no efect.

The execution of any construct raises Storage_Error if there is insufﬁcient storage for that execution. The amount of storage needed for the execution of constructs is unspeciﬁed.

Ramiﬁcation: Note that any execution whatsoever can raise Storage_Error. This allows much implementation freedom in storage management.

Examples

Examples of user-deﬁned exception declarations:

Singular : exception;
Error : exception;
Overflow, Underﬂow : exception;

Inconsistencies With Ada 83

The exception Numeric_Error is now deﬁned in the Obsolescent features Annex, as a rename of Constraint_Error. All checks that raise Numeric_Error in Ada 83 instead raise Constraint_Error in Ada 95. To increase upward compatibility, we also changed the rules to allow the same exception to be named more than once by a given handler. Thus, when ConstraintError | Numeric_Error => will remain legal in Ada 95, even though Constraint Error and Numeric_Error now denote the same exception. However, it will not be legal to have separate handlers for Constraint_Error and Numeric_Error. This change is inconsistent in the rare case that an existing program explicitly raises Numeric_Error at a point where there is a handler for Constraint_Error; the exception will now be caught by that handler.

Wording Changes from Ada 83

We explicitly deﬁne elaboration for exception_declarations.

Extensions to Ada 2005

{AI05-0183-1} An optional aspect speciﬁcation can be used in a exception_declaration. This is described in 13.1.1.

11.2 Exception Handlers

[The response to one or more exceptions is speciﬁed by an exception Handler.]

Syntax

handled_sequence_of_statements ::= sequence_of_statements [exception
exception_handler {exception_handler}]}

exception_handler ::= when [choice_parameter_specification:] exception_choice {exception_choice} => sequence_of_statements

choice_parameter_specification ::= deﬁning_identifier
exception_choice ::= exception_name | others

To be honest: “Handler” is an abbreviation for “exception_handler.”

{AI05-0299-1} Within this clause section, we sometimes abbreviate “exception_choice” to “choice.”

Legality Rules

A choice with an exception_name covers the named exception. A choice with others covers all exceptions not named by previous choices of the same handled_sequence_of_statements. Two choices in different exception_handlers of the same handled_sequence_of_statements shall not cover the same exception.

Ramification: Two exception_choice of the same exception_handler may cover the same exception. For example, given two renaming declarations in separate packages for the same exception, one may nevertheless write, for example, “when Ada.Text_IO.Data_Error | My_Seq_IO.Data_Error =>”.

An others choice even covers exceptions that are not visible at the place of the handler. Since exception raising is a dynamic activity, it is entirely possible for an others handler to handle an exception that it could not have named.

A choice with others is allowed only for the last handler of a handled_sequence_of_statements and as the only choice of that handler.

An exception_name of a choice shall not denote an exception declared in a generic formal package.

Reason: This is because the compiler doesn’t know the identity of such an exception, and thus can’t enforce the coverage rules.

Static Semantics

A choice_parameter_specification declares a choice parameter, which is a constant object of type Exception_Occurrence (see 11.4.1). During the handling of an exception occurrence, the choice parameter, if any, of the handler represents the exception occurrence that is being handled.

Dynamic Semantics

The execution of a handled_sequence_of_statements consists of the execution of the sequence_of_statements. [The optional handlers are used to handle any exceptions that are propagated by the sequence_of_statements.]

Examples

Example of an exception handler:

begin
  Open(File, In_File, "input.txt"); -- see A.8.2
exception
  when E : Name_Error =>
    Put("Cannot open input file : ");
    Put_Line(Exception_Message(E)); -- see 11.4.1
    raise;
end;

Extensions to Ada 83

The syntax rule for exception_handler is modified to allow a choice_parameter_specification.

{AI95-00114-01} Different exception_choice of the same exception_handler may cover the same exception. This allows for “when Numeric_Error | Constraint_Error =>” even though Numeric_Error is a rename of Constraint_Error. This also allows one to “with” two different I/O packages, and then write, for example, “when Ada.Text_IO.Data_Error | My_Seq_IO.Data_Error =>” even though these might both be renames of the same exception.
Wording Changes from Ada 83

12.c The syntax rule for `handled_sequence_of_statements` is new. These are now used in all the places where handlers are allowed. This obviates the need to explain (in Clauses Sections 5, 6, 7, and 9) what portions of the program are handled by the handlers. Note that there are more such cases in Ada 95.

12.d The syntax rule for `choice_parameter_specification` is new.

11.3 Raise Statements

[A `raise_statement` raises an exception.]

Syntax

{AI95-00361-01} `raise_statement ::= raise;`

{AI95-00361-01} `raise_exception_name [with string_expression]; raise [exception_name];`

Legality Rules

3 The name, if any, in a `raise_statement` shall denote an exception. A `raise_statement` with no `exception_name` (that is, a `re-raise_statement`) shall be within a handler, but not within a body enclosed by that handler.

Name Resolution Rules

{AI95-00361-01} The `expression`, if any, in a `raise_statement`, is expected to be of type String.

Dynamic Semantics

4 To raise an exception is to raise a new occurrence of that exception[, as explained in 11.4]. For the execution of a `raise_statement` with an `exception_name`, the named exception is raised. [If a `string_expression` is present, the `expression` is evaluated and its value is associated with the exception occurrence.] For the execution of a re-raise statement, the exception occurrence that caused transfer of control to the innermost enclosing handler is raised [again].

Proof: {AI95-00361-01} The definition of Exceptions.Exception_Message includes a statement that the string is returned (see 11.4.1). We describe the use of the string here so that we don't have an unexplained parameter in this subclause.

Implementation Note: For a re-raise statement, the implementation does not create a new Exception_Occurrence, but instead propagates the same Exception_Occurrence value. This allows the original cause of the exception to be determined.

Examples

Examples of `raise statements`:

{AI95-00433-01} `raise Ada.IO_Exceptions.Name_Error;` -- see A.13

`raise Queue_Error with "Buffer Full";` -- see 9.11

`raise;` -- re-raise the current exception

Wording Changes from Ada 83

7.a The fact that the name in a `raise_statement` has to denote an exception is not clear from RM83. Clearly that was the intent, since the italicized part of the syntax rules so indicate, but there was no explicit rule. RM83-1.5(11) doesn't seem to give the italicized parts of the syntax any force.

Extensions to Ada 95

{AI95-00361-01} The syntax of a `raise_statement` is extended to include a string message. This is more convenient than calling Exceptions.Exception_Message (exception_name/Identity, string_expression), and should encourage the use of message strings when raising exceptions.
11.4 Exception Handling

When an exception occurrence is raised, normal program execution is abandoned and control is transferred to an applicable exception_handler, if any. To handle an exception occurrence is to respond to the exceptional event. To propagate an exception occurrence is to raise it again in another context; that is, to fail to respond to the exceptional event in the present context.

**Ramification:** In other words, if the execution of a given construct raises an exception, but does not handle it, the exception is propagated to an enclosing execution (except in the case of a task_body). Propagation involves re-raising the same exception occurrence (assuming the implementation has not taken advantage of the Implementation Permission of 11.3). For example, calling an entry of an uncallable task raises Tasking_Error; this is not propagation.

Dynamic Semantics

Within a given task, if the execution of construct $a$ is defined by this International Standard to consist (in part) of the execution of construct $b$, then while $b$ is executing, the execution of $a$ is said to dynamically enclose the execution of $b$. The innermost dynamically enclosing execution of a given execution is the dynamically enclosing execution that started most recently.

**To be honest:** If the execution of $a$ dynamically encloses that of $b$, then we also say that the execution of $b$ is included in the execution of $a$.

**Ramification:** Examples: The execution of an if_statement dynamically encloses the evaluation of the condition after the if (during that evaluation). (Recall that "execution" includes both "elaboration" and "evaluation", as well as other executions.) The evaluation of a function call dynamically encloses the execution of the sequence_of_statements of the function body (during that execution). Note that, due to recursion, several simultaneous executions of the same construct can be occurring at once during the execution of a particular task.

Dynamically enclosing is not defined across task boundaries; a task's execution does not include the execution of any other tasks.

Dynamically enclosing is only defined for executions that are occurring at a given moment in time; if an if_statement is currently executing the sequence_of_statements after then, then the evaluation of the condition is no longer dynamically enclosed by the execution of the if_statement (or anything else).

When an exception occurrence is raised by the execution of a given construct, the rest of the execution of that construct is abandoned; that is, any portions of the execution that have not yet taken place are not performed. The construct is first completed, and then left, as explained in 7.6.1. Then:

- If the construct is a task_body, the exception does not propagate further;

  **Ramification:** When an exception is raised by the execution of a task_body, there is no dynamically enclosing execution, so the exception does not propagate any further. If the exception occurred during the activation of the task, then the activator raises Tasking_Error, as explained in 9.2, "Task Execution - Task Activation", but we don't define that as propagation; it's a special rule. Otherwise (the exception occurred during the execution of the handled_sequence_of_statements of the task), the task silently disappears. Thus, abnormal termination of tasks is not always considered to be an error.

- If the construct is the sequence_of_statements of a handled_sequence_of_statements that has a handler with a choice covering the exception, the occurrence is handled by that handler;

- Otherwise, the occurrence is propagated to the innermost dynamically enclosing execution, which means that the occurrence is raised again in that context.

  **To be honest:** As shorthands, we refer to the propagation of an exception, and the propagation by a construct, if the execution of the construct propagates an exception occurrence.

When an occurrence is handled by a given handler, the choice_parameter_specification, if any, is first elaborated, which creates the choice parameter and initializes it to the occurrence. Then, the sequence_of_statements of the handler is executed; this execution replaces the abandoned portion of the execution of the sequence_of_statements.
Ramification: {AI95-00318-02} This “replacement” semantics implies that the handler can do pretty much anything the abandoned sequence could do; for example, in a function, the handler can execute a `return statement` that applies to the function.

#### 11.4.1 The Package Exceptions

**Static Semantics**

The following language-defined library package exists:

```ada
package Ada.Exceptions is
    pragma Preelaborate(Exceptions);
    type Exception_Id is private;
    pragma Preelaborable_Initialization(Exception_Id);
    function Exception_Name(Id : Exception_Id) return String;
    function Wide_Exception_Name(Id : Exception_Id) return Wide_String;
    function Wide_Wide_Exception_Name(Id : Exception_Id) return Wide_Wide_String;

    type Exception_Occurrence is limited private;
    pragma Preelaborable_Initialization(Exception_Occurrence);
    type Exception_Occurrence_Access is access all Exception_Occurrence;
    Null_Occurrence : constant Exception_Occurrence;

    procedure Raise_Exception(E : in Exception_Id;
                              Message : in String := "");
    withpragma No_Return(Raise_Exception);
    function Exception_Message(X : Exception_Occurrence) return String;
    procedure Reraise_Occurrence(X : in Exception_Occurrence);

    function Exception_Identity(X : Exception_Occurrence) return Exception_Id;
    function Exception_Name(X : Exception_Occurrence) return String;
    -- Same as Exception_Name(Exception_Identity(X)).
    function Wide_Exception_Name(X : Exception_Occurrence) return Wide_String;
    -- Same as Wide_Exception_Name(Exception_Identity(X)).
    function Wide_Wide_Exception_Name(X : Exception_Occurrence) return Wide_Wide_String;
    -- Same as Wide_Wide_Exception_Name(Exception_Identity(X)).
    function Exception_Information(X : Exception_Occurrence) return String;

    procedure Save_Occurrence(Target : out Exception_Occurrence;
                               Source : in Exception_Occurrence);
    function Save_Occurrence(Source : Exception_Occurrence) return Exception_Occurrence_Access;

private
    -- not specified by the language
end Ada.Exceptions;
```

NOTES

1. Note that exceptions raised in a declarative_part of a body are not handled by the handlers of the handled_sequence_of_statements of that body.
Each distinct exception is represented by a distinct value of type Exception_Id. Null_Id does not represent any exception, and is the default initial value of type Exception_Id. Each occurrence of an exception is represented by a value of type Exception_Occurrence. Null_Occurrence does not represent any exception occurrence, and is the default initial value of type Exception_Occurrence.

For a prefix E that denotes an exception, the following attribute is defined:

E’Identity  

E’Identity returns the unique identity of the exception. The type of this attribute is Exception_Id.

Ramification: In a distributed program, the identity is unique across an entire program, not just across a single partition. Exception propagation works properly across RPC’s. An exception can be propagated from one partition to another, and then back to the first, where its identity is known.

Raise_Exception raises a new occurrence of the identified exception. In this case Exception_Message returns the Message parameter of Raise_Exception. For a raise_statement with an exception_name, Exception_Message returns implementation-defined information about the exception occurrence. Reraise_Occurrence reraises the specified exception occurrence.

Exception_Message returns the message associated with the given Exception_Occurrence. For an occurrence raised by a call to Raise_Exception, the message is the Message parameter passed to Raise_Exception. For the occurrence raised by a raise_statement with an exception_name and a string_expression, the message is the string_expression. For the occurrence raised by a raise_statement with an exception_name but without a string_expression, the message is a string giving implementation-defined information about the exception occurrence. For an occurrence originally raised in some other manner (including by the failure of a language-defined check), the message is an unspecified string. In all cases, Exception_Message returns a string with lower bound 1.

Implementation defined: The information returned by Exception_Message.

Discussion: There is Implementation Advice about the contents of this string for language-defined checks.

Ramification: Given an exception E, the raise_statement:

raise E;

is equivalent to this call to Raise_Exception:

Raise_Exception(E’Identity, Message => implementation-defined-string);

Similarly, the raise_statement:

raise E with "some information";

is equivalent to this call to Raise_Exception:

Raise_Exception(E’Identity, Message => "some information");

Reraise_Occurrence reraises the specified exception occurrence.

Ramification: The following handler:

when others =>
  Cleanup;
  raise;

is equivalent to this one:

when X : others =>
  Cleanup;
  Reraise_Occurrence(X);

Exception_Identity returns the identity of the exception of the occurrence.
The `Wide_Wide_Exception_Name` function returns the full expanded name of the exception, in upper case, starting with a root library unit. For an exception declared immediately within package `Standard`, the `defining_identifier` is returned. The result is implementation defined if the exception is declared within an unnamed `block_statement`.

**Ramification:** See the Implementation Permission below.

**To be honest:** This name, as well as each prefix of it, does not denote a `renaming_declaration`.

**Implementation defined:** The result of `Exceptions.Wide_Wide_Exception_Name` for exceptions declared within an unnamed `block_statement`.

**Ramification:** Note that we're talking about the name of the exception, not the name of the occurrence.

The `Exception_Name` functions (respectively, `Wide_Exception_Name`) return the same sequence of graphic characters as that defined for `Wide_Wide_Exception_Name`, if all the graphic characters are defined in `Character` (respectively, `Wide_Character`); otherwise, the sequence of characters is implementation defined, but no shorter than that returned by `Wide_Wide_Exception_Name` for the same value of the argument.

**Implementation defined:** The sequence of characters of the value returned by `Exceptions.Exception_Name` (respectively, `Exceptions.Wide_Exception_Name`) when some of the graphic characters of `Exceptions.Wide_Exception_Name` are not defined in `Character` (respectively, `Wide_Character`).

The string returned by the `Exception_Name`, `Wide_Exception_Name`, and `Wide_Wide_Exception_Name` functions has lower bound 1.

**Implementation defined:** The information returned by `Exception_Information`.

`Raise_Exception` and `Reraise_Occurrence` have no effect in the case of `Null_Id` or `Null_Occurrence`. `Raise_Exception` and `Exception_Name` raise `Constraint_Error` for a `Null_Id`. `Exception_Message`, `Exception_Name`, and `Exception_Identity` applied to `Null_Occurrence` returns `Null_Id`, `Exception_Message`, `Exception_Identity`, `Exception_Name`, and `Exception_Information` raise `Constraint_Error` for a `Null_Id` or `Null_Occurrence`.

**Ramification:** `Null_Occurrence` can be tested for by comparing `Exception_Identity(Occurrence)` to `Null_Id`.

**Discussion:** `Raise_Exception` was changed so that it always raises an exception and thus can be a No_Return procedure. A similar change was not made for `Reraise_Occurrence`, as doing so was determined to be a significant incompatibility. It is not unusual to pass an `Exception_Occurrence` to other code to delay raising it. If there was no exception, passing `Null_Occurrence` works fine (nothing is raised). Moreover, as there is no test for `Null_Occurrence` in Ada 95, this is the only way to write such code without using additional flags. Breaking this sort of code is unacceptable.

The `Save_Occurrence` procedure copies the Source to the Target. The `Save_Occurrence` function uses an allocator of type `Exception_Occurrence_Access` to create a new object, copies the Source to this new object, and returns an access value designating this new object; [the result may be deallocated using an instance of `Unchecked_Deallocation`].

**Ramification:** It's OK to pass `Null_Occurrence` to the `Save_Occurrence` subprograms; they don't raise an exception, but simply save the `Null_Occurrence`.

**Ramification:** This routines are used to define the stream attributes (see 13.13.2) for `Exception_Occurrence`.

The identity of the exception, as well as the `Exception_Name` and `Exception_Message`, have to be preserved across partitions.
The string returned by Exception_Name or Exception_Message on the result of calling the Read attribute on a given stream has to be the same as the value returned by calling the corresponding function on the exception occurrence that was written into the stream with the Write attribute. The string returned by Exception_Information need not be the same, since it is implementation defined anyway.

**Reason:** This is important for supporting writing exception occurrences to external files for post-mortem analysis, as well as propagating exceptions across remote subprogram calls in a distributed system (see E.4).

### Implementation Requirements

\{AI95-00438-01\} The implementation of the Write attribute (see 13.13.2) of Exception_Occurrence shall support writing a representation of an exception occurrence to a stream; the implementation of the Read attribute of Exception_Occurrence shall support reconstructing an exception occurrence from a stream (including one written in a different partition).

**Ramification:** The identity of the exception, as well as the Exception_Name and Exception_Message, have to be preserved across partitions.

The string returned by Exception_Name or Exception_Message on the result of calling the Read attribute on a given stream has to be the same as the value returned by calling the corresponding function on the exception occurrence that was written into the stream with the Write attribute. The string returned by Exception_Information need not be the same, since it is implementation defined anyway.

**Reason:** This is important for supporting writing exception occurrences to external files for post-mortem analysis, as well as propagating exceptions across remote subprogram calls in a distributed system (see E.4).

**Paragraph 16 was deleted.**

### Implementation Permissions

An implementation of Exception_Name in a space-constrained environment may return the defining_identifier instead of the full expanded name.

The string returned by Exception_Message may be truncated (to no less than 200 characters) by the Save_Occurrence procedure [(not the function)], the Reraise_Occurrence procedure, and the re-raise statement.

**Reason:** The reason for allowing truncation is to ease implementations. The reason for choosing the number 200 is that this is the minimum source line length that implementations have to support, and this feature seems vaguely related since it's usually a “one-liner”. Note that an implementation is allowed to do this truncation even if it supports arbitrarily long lines.

### Implementation Advice

Exception_Message (by default) and Exception_Information should produce information useful for debugging. Exception_Message should be short (about one line), whereas Exception_Information can be long. Exception_Message should not include the Exception_Name. Exception_Information should include both the Exception_Name and the Exception_Message.

**Implementation Advice:** Exception_Information should provide information useful for debugging, and should include the Exception_Name and Exception_Message.

**Implementation Advice:** Exception_Message by default should be short, provide information useful for debugging, and should not include the Exception_Name.

**Reason:** It may seem strange to define two subprograms whose semantics is implementation defined. The idea is that a program can print out debugging/error-logging information in a portable way. The program is portable in the sense that it will work in any implementation; it might print out different information, but the presumption is that the information printed out is appropriate for debugging/error analysis on that system.

**Implementation Note:** As an example, Exception_Information might include information identifying the location where the exception occurred, and, for predefined exceptions, the specific kind of language-defined check that failed. There is an implementation trade-off here, between how much information is represented in an Exception_Occurrence, and how much can be passed through a re-raise.
The string returned should be in a form suitable for printing to an error log file. This means that it might need to contain line-termination control characters with implementation-defined I/O semantics. The string should neither start nor end with a newline.

If an implementation chooses to provide additional functionality related to exceptions and their occurrences, it should do so by providing one or more children of Ada.Exceptions.

Note that exceptions behave as if declared at library level; there is no “natural scope” for an exception; an exception always exists. Hence, there is no harm in saving an exception occurrence in a data structure, and re-raising it later. The reraise has to occur as part of the same program execution, so saving an exception occurrence in a file, reading it back in from a different program execution, and then reraising it is not required to work. This is similar to I/O of access types. Note that it is possible to use RPC to propagate exceptions across partitions.

Here's one way to implement Exception_Occurrence in the private part of the package. Using this method, an implementation need store only the actual number of characters in exception messages. If the user always uses small messages, then exception occurrences can be small. If the user never uses messages, then exception occurrences can be smaller still:

```ada
type Exception_Occurrence(Message_Length : Natural := 200) is
  limited record
    Id : Exception_Id;
    Message : String(1..Message_Length);
  end record;
```

At the point where an exception is raised, an Exception_Occurrence can be allocated on the stack with exactly the right amount of space for the message — none for an empty message. This is just like declaring a constrained object of the type:

```ada
Temp : Exception_Occurrence(10); -- for a 10-character message
```

After finding the appropriate handler, the stack can be cut back, and the Temp copied to the right place. This is similar to returning an unknown-sized object from a function. It is not necessary to allocate the maximum possible size for every Exception_Occurrence. If, however, the user declares an Exception_Occurrence object, the discriminant will be permanently set to 200. The Save_Occurrence procedure would then truncate the Exception_Message. Thus, nothing is lost until the user tries to save the occurrence. If the user is willing to pay the cost of heap allocation, the Save_Occurrence function can be used instead.

Note that any arbitrary-sized implementation-defined Exception_Information can be handled in a similar way. For example, if the Exception_Occurrence includes a stack traceback, a discriminant can control the number of stack frames stored. The traceback would be truncated or entirely deleted by the Save_Occurrence procedure — as the implementation sees fit.

If the internal representation involves pointers to data structures that might disappear, it would behoove the implementation to implement it as a controlled type, so that assignment can either copy the data structures or else null out the pointers. Alternatively, if the data structures being pointed at are in a task control block, the implementation could keep a unique sequence number for each task, so it could tell when a task's data structures no longer exist.

Using the above method, heap space is never allocated unless the user calls the Save_Occurrence function.

An alternative implementation would be to store the message strings on the heap when the exception is raised. (It could be the global heap, or it could be a special heap just for this purpose — it doesn't matter.) This representation would be used only for choice parameters. For normal user-defined exception occurrences, the Save Occurrence procedure would copy the message string into the occurrence itself, truncating as necessary. Thus, in this implementation, Exception_Occurrence would be implemented as a variant record:

```ada
type Exception_Occurrence_Kind is (Normal, As_Choice_Param);

type Exception_Occurrence(Kind : Exception_Occurrence_Kind := Normal) is
  limited record
    case Kind is
      when Normal =>
        ... -- space for 200 characters
      when As_Choice_Param =>
        ... -- pointer to heap string
    end case;
  end record;
```

Exception_Occurrences created by the run-time system during exception raising would be As_Choice_Param. User-declared ones would be Normal — the user cannot see the discriminant, and so cannot set it to As_Choice_Param. The strings in the heap would be freed upon completion of the handler.

This alternative implementation corresponds to a heap-based implementation of functions returning unknown-sized results.

One possible implementation of Reraise_Occurrence is as follows:
procedure Reraise_Occurrence(X : in Exception_Occurrence) is
begin
  Raise_Exception(Identity(X), Exception_Message(X));
end Reraise_Occurrence;

However, some implementations may wish to retain more information across a re-raise — a stack traceback, for example.

**Ramification:** Note that Exception_Occurrence is a definite subtype. Hence, values of type Exception_Occurrence may be written to an error log for later analysis, or may be passed to subprograms for immediate error analysis.

This paragraph was deleted **Implementation Note:**  
If an implementation chooses to have a mode in which it supports non-Latin-1 characters in identifiers, then it needs to define what the above functions return in the case where the name of an exception contains such a character.

**Extensions to Ada 83**

The Identity attribute of exceptions is new, as is the package Exceptions.

**Inconsistencies With Ada 95**

\{AI95-00241-01\} **Amendment Correction:** Exception_Identity of an Exception_Occurrence now is defined to return Null_Id for Null_Occurrence, rather than raising Constraint_Error. This provides a simple way to test for Null_Occurrence. We expect that programs that need Constraint_Error raised will be very rare; they can be easily fixed by explicitly testing for Null_Id or by using Exception_Name instead.

\{AI95-00378-01\}  \{AI95-00417-01\} **Amendment Correction:** We now define the lower bound of the string returned from \[Wide_\text{Exception_Name}, \text{Exception_Message}, \text{Exception_Information}\]. This makes working with the returned string easier, and is consistent with many other string-returning functions in Ada. This is technically an inconsistency; if a program depended on some other lower bound for the string returned from one of these functions, it could fail when compiled with Ada 2005. Such code is not portable even between Ada 95 implementations, so it should be very rare.

\{AI95-00446-01\} **Amendment Correction:** Raise_Exception now raises Constraint_Error if passed Null_Id. This means that it always raises an exception, and thus we can apply pragma No_Return to it. We expect that programs that call Raise_Exception with Null_Id will be rare, and programs that do that and expect no exception to be raised will be rarer; such programs can be easily fixed by explicitly testing for Null_Id before calling Raise_Exception.

**Incompatibilities With Ada 95**

\{AI95-00400-01\}  \{AI95-00438-01\}  \{AI05-0005-1\} Functions \text{Wide_Exception_Name} and \text{Wide_Wide_Exception_Name}, and procedures \text{Read_Exception_Occurrence} and \text{Write_Exception_Occurrence} are newly added to \text{Exceptions}. If \text{Exceptions} is referenced in a \text{use_clause}, and an entity \text{E} with the same \text{defining_identifier} as a new entity in \text{Exceptions} is defined in a package that is also referenced in a \text{use_clause}, the entity \text{E} may no longer be use-visible, resulting in errors. This should be rare and is easily fixed if it does occur.

**Extensions to Ada 95**

\{AI95-00362-01\} The package \text{Exceptions} is preelaborated, and types \text{Exception_Id} and \text{Exception_Occurrence} have preelaborable initialization, allowing this package to be used in preelaborated units.

**Wording Changes from Ada 95**

\{AI95-00361-01\} The meaning of \text{Exception_Message} is reworded to reflect that the string can come from a \text{raise_statement} as well as a call of \text{Raise_Exception}.

\{AI95-00400-01\} **Added**: \text{Wide_Exception_Name} and \text{Wide_Wide_Exception_Name} because identifiers can now contain characters outside of Latin-1.

**Wording Changes from Ada 2005**

\{AI05-0043-1\} **Correction:** Added explicit wording that the exception message for language-defined checks is unspecified. The old wording appeared inclusive, but it was not.

### 11.4.2 Pragmas Assert and Assertion_Policy

\{AI95-00286-01\}  \{AI05-0274-1\} Pragma Assert is used to assert the truth of a \text{boolean} boolean expression at any point within a sequence of declarations or statements. Pragma Assertion_Policy is used
to control whether such assertions are to be ignored by the implementation, checked at run-time, or handled in some implementation-defined manner.

Glossary entry: A predicate is an assertion that is expected to be True for all objects of a given subtype.

Glossary entry: A precondition is an assertion that is expected to be True when a given subprogram is called.

Glossary entry: A postcondition is an assertion that is expected to be True when a given subprogram returns normally.

Glossary entry: A invariant is an assertion that is expected to be True for all objects of a given private type when viewed from outside the defining package.

Glossary entry: An assertion is a boolean expression that appears in any of the following: a pragma Assert, a predicate, a precondition, a postcondition, an invariant, a constraint, or a null exclusion. An assertion is expected to be True at run time at certain specified places.

Pragma Assertion_Policy is used to control whether assertions are to be ignored by the implementation, checked at run time, or handled in some implementation-defined manner.

Syntax

The form of a pragma Assert is as follows:

`pragma Assert([Check =>] boolean_expression[, [Message =>] string_expression]);`

A pragma Assert is allowed at the place where a declarative item or a statement is allowed.

The form of a pragma Assertion_Policy is as follows:

`pragma Assertion_Policy(policy_identifier);`

A pragma Assertion_Policy is allowed only immediately within a declarative part, immediately within a package specification, or as a configuration pragma.

Name Resolution Rules

The expected type for the boolean_expression of a pragma Assert is any boolean type. The expected type for the string_expression of a pragma Assert is type String.

Reason: We allow any boolean type to be like if statements and other conditionals; we only allow String for the message in order to match raise statements.

Legality Rules

The assertion_aspect_mark of a pragma Assertion_Policy shall be one of Assert, Static_Predicate, Dynamic_Predicate, Pre, Pre'Class, Post, Post'Class, Type_Invariant, Type_Invariant'Class, or some implementation defined aspect_mark. The policy_identifier of a pragma Assertion_Policy shall be either Check, Ignore, or some implementation-defined identifier.

Implementation defined: Implementation-defined policy_identifiers and assertion_aspect_marks allowed in a pragma Assertion_Policy.

Static Semantics

A pragma Assertion_Policy determines for each assertion aspect named in the pragma_argument_associations whether assertions of the given aspect are to be enforced by a run-time check. The policy_identifier Check requires that assertion expressions of the given aspect be checked that they evaluate to True at the points specified for the given aspect; the policy_identifier Ignore
requires that the assertion expression not be evaluated at these points, and the run-time checks not be performed. [Note that for subtype predicate aspects (see 3.2.4), even when the applicable Assertion Policy is Ignore, the predicate will still be evaluated as part of membership tests and Valid attribute references, and if static, will still have an effect on loop iteration over the subtype, and the selection of case statement alternatives and variants.]

A configuration pragma that specifies the assertion policy in effect for the compilation units to which it applies. Different policies may apply to different compilation units within the same partition. The default assertion policy is implementation defined.

{AI05-0290-1} If no assertion aspect marks are specified in the pragma, the specified policy applies to all assertion aspects.

{AI05-0290-1} A pragma Assertion Policy applies to the named assertion aspects in a specific region, and applies to all assertion expressions specified in that region. A pragma Assertion Policy given in a declarative part or immediately within a package specification applies from the place of the pragma to the end of the innermost enclosing declarative region. The region for a pragma Assertion Policy given as a configuration pragma is the declarative region for the entire compilation unit (or units) to which it applies.

{AI05-0290-1} If a pragma Assertion Policy applies to a generic instantiation, then the pragma Assertion Policy applies to the entire instance.

Ramification: This means that an Assertion Policy pragma that occurs in a scope enclosing the declaration of a generic unit but not also enclosing the declaration of a given instance of that generic unit will not apply to assertion expressions occurring within the given instance.

{AI05-0290-1} If multiple Assertion Policy pragmas apply to a given construct for a given assertion aspect, the assertion policy is determined by the one in the innermost enclosing region of a pragma Assertion Policy specifying a policy for the assertion aspect. If no such Assertion Policy pragma exists, the policy is implementation defined.

Implementation defined: The default assertion policy.

{AI95-00286-01} The following language-defined library package exists:

```ada
package Ada.Assertions is
    pragma Pure(Assertions);
    Assertion_Error : exception;
    procedure Assert (Check : in Boolean);
    procedure Assert (Check : in Boolean; Message : in String);
end Ada.Assertions;
```

{AI95-00286-01} {AI05-0290-1} A compilation unit containing a check for an assertion (including a pragma Assert) has a semantic dependence on the Assertions library unit.

This paragraph was deleted. {AI95-00286-01} {AI05-0290-1} The assertion policy that applies to a generic unit also applies to all its instances.

Dynamic Semantics

{AI95-00286-01} {AI05-0290-1} An assertion policy specifies how a pragma Assert is interpreted by the implementation. If the assertion policy is Ignore at the point of a pragma Assert, the pragma is ignored. If performing checks is required by the Assert assertion policy in effect Check at the placepoint of a pragma Assert, the elaboration of the pragma consists of evaluating the boolean expression, and if the result is False, evaluating the Message argument, if any, and raising the exception Assertions.Assertion_Error, with a message if the Message argument is provided.

11.4.2 Pragmas Assert and Assertion_Policy

Calling the procedure Assertions.Assert without a Message parameter is equivalent to:

```ada
if Check = False then
  raise Ada.Assertions.Assertion_Error;
end if;
```

Calling the procedure Assertions.Assert with a Message parameter is equivalent to:

```ada
if Check = False then
  raise Ada.Assertions.Assertion_Error with Message;
end if;
```

The procedures Assertions.Assert have these effects independently of the assertion policy in effect.

Bounded (Run-Time) Errors

It is a bounded error to invoke a potentially blocking operation (see 9.5.1) during the evaluation of an assertion expression associated with a call on, or return from, a protected operation. If the bounded error is detected, Program_Error is raised. If not detected, execution proceeds normally, but if it is invoked within a protected action, it might result in deadlock or a (nested) protected action.

Implementation Permissions

Assertion_Error may be declared by renaming an implementation-defined exception from another package.

Reason: This permission is intended to allow implementations which had an implementation-defined Assert pragma to continue to use their originally defined exception. Without this permission, such an implementation would be incorrect, as Exception Name would return the wrong name.

Implementations may define their own assertion policies.

If the result of a function call in an assertion is not needed to determine the value of the assertion expression, an implementation is permitted to omit the function call. [This permission applies even if the function has side effects.]

An implementation need not allow the specification of an assertion expression if the evaluation of the expression has a side effect such that an immediate reevaluation of the expression could produce a different value. Similarly, an implementation need not allow the specification of an assertion expression that is checked as part of a call on or return from a callable entity C, if the evaluation of the expression has a side effect such that the evaluation of some other assertion expression associated with the same call of (or return from) C could produce a different value than it would if the first expression had not been evaluated.

Ramification: This allows an implementation to reject such assertions. To maximize portability, assertions should not include expressions that contain these sorts of side effects.

Discussion: The intended effect of the second part of the rule (the part starting with “Similarly”) is that an evaluation of the involved assertion expressions (subtype predicates, type invariants, preconditions and postconditions) in any order yields identical results.

The rule is intended to apply to all of the assertion expressions that are evaluated at the start of call (and similarly for the assertion expressions that are evaluated during the return from a call), but not other assertions actually given in the body, nor between the assertions checked at the start and end of the call. Specifically, a side effect that alters a variable in a function called from a precondition expression that changes the result of a postcondition expression of the same subprogram does not trigger these rules unless it also changes the value of a reevaluation of the precondition expression.

NOTES

2 Normally, the boolean expression in a pragma Assert should not call functions that have significant side effects when the result of the expression is True, so that the particular assertion policy in effect will not affect normal operation of the program.
Extensions to Ada 95

\{AI95-00286-01\} Pragmas Assert and Assertion Policy, and package Assertions are new.

Incompatibilities With Ada 2005

\{AI05-0274-1\} There now is an Implementation Permission to reject an assertion expression that calls a function that has a side effect such that an immediate reevaluation of the expression could produce a different value. This means that a \texttt{pragma Assert} that works in Ada 2005 might be illegal in Ada 2012 in the unlikely event that the compiler detected such an error. This should be unlikely to occur in practice and it is considered a good thing, as the original expression was tricky and probably was not portable (as order of evaluation is unspecified within an expression). Moreover, no compiler is \textit{required} to reject such expressions, so there is no need for any compiler to change behavior.

Extensions to Ada 2005

\{AI05-0290-1\} Assertion Policy pragmas are now allowed in more places and can specify behavior for individual kinds of assertions.

### 11.4.3 Example of Exception Handling

#### Examples

Exception handling may be used to separate the detection of an error from the response to that error:

\{AI95-00433-01\} \texttt{with Ada.Exceptions;}

\texttt{use Ada;}

\texttt{package File_System is}

\texttt{type File_Handle is limited private;}

\texttt{File_Not_Found : exception;}

\texttt{procedure Open(F : in out File_Handle; Name : String); -- raises File_Not_Found if named file does not exist}

\texttt{End_Of_File : exception;}

\texttt{procedure Read(F : in out File_Handle; Data : out Data_Type); -- raises End_Of_File if the file is not open}

\texttt{end File_System;}

\{AI95-00433-01\} \texttt{package body File_System is}

\texttt{procedure Open(F : in out File_Handle; Name : String) is}

\texttt{begin}

\texttt{if File_Exists(Name) then}

\texttt{...}

\texttt{else}

\texttt{raise Exceptions.Raise_Exception(File_Not_Found with "Id:entity, "File not found: " & Name & "," );}

\texttt{end if;}

\texttt{end Open;}

\texttt{procedure Read(F : in out File_Handle; Data : out Data_Type) is}

\texttt{begin}

\texttt{if F.Current_Position \le F.Last_Position then}

\texttt{...}

\texttt{else}

\texttt{raise End_Of_File;}

\texttt{end if;}

\texttt{end Read;}

\texttt{...}

\texttt{end File_System;
with Ada.Text_IO;
with Ada.Exceptions;
with File_System; use File_System;
use Ada;
procedure Main is
begin
  ... -- call operations in File_System

exception
  when End_Of_File =>
    Close(Some_File);
  when Not_Found_Error : File_Not_Found =>
    Text_IO.Put_Line(Exceptions.Exception_Message(Not_Found_Error));
  when The_Error : others =>
    if Verbosity_Desired then
      Text_IO.Put_Line(Exceptions.Exception_Information(The_Error));
    else
      Text_IO.Put_Line(Exceptions.Exception_Name(The_Error));
      Text_IO.Put_Line(Exceptions.Exception_Message(The_Error));
    end if;
    raise;
end Main;

In the above example, the File_System package contains information about detecting certain exceptional situations, but it does not specify how to handle those situations. Procedure Main specifies how to handle them; other clients of File_System might have different handlers, even though the exceptional situations arise from the same basic causes.

Wording Changes from Ada 83

11.5 Suppressing Checks

Checking pragmas give instructions to an implementation on handling language-defined checks. A pragma Suppress gives permission to an implementation to omit certain language-defined checks, while a pragma Unsuspend revokes the permission to omit checks.

A language-defined check (or simply, a “check”) is one of the situations defined by this International Standard that requires a check to be made at run time to determine whether some condition is true. A check fails when the condition being checked is False, causing an exception to be raised.

Discussion: All such checks are defined under “Dynamic Semantics” in clauses and subclauses throughout the standard.

Syntax

The forms of checking pragmas are as follows:

pragma Suppress(identifier [, [On =>] name]);

pragma Unsuspend(identifier);

A checking pragma is allowed only immediately within a declarative_part, immediately within a package_specification, or as a configuration pragma.

Legality Rules

The identifier shall be the name of a check. The name (if present) shall statically denote some entity.
This paragraph was deleted.\{AI95-00224-01\} For a pragma Suppress that is immediately within a package_specification and includes a name, the name shall denote an entity (or several overloaded subprograms) declared immediately within the package_specification.

Static Semantics

\{AI95-00224-01\} A checking pragma applies to the named check in a specific region, and applies to all entities in that region. A checking pragma given in a declarative_part or immediately within a package_specification applies from the place of the pragma to the end of the innermost enclosing declarative region. The region for a checking pragma given as a configuration pragma is the declarative region for the entire compilation unit (or units) to which it applies.

\{AI95-00224-01\} \{AI95-00229-1\} \{AI95-00290-1\} If a checking pragma applies to a generic instantiation, then the checking pragma also applies to the entire instance. If a checking pragma applies to a call to a subprogram that has a pragma Inline applied to it, then the checking pragma also applies to the inlined subprogram body.

Ramification: \{AI95-00290-1\} This means that a Suppress pragma that occurs in a scope enclosing the declaration of a generic unit but not also enclosing the declaration of a given instance of that generic unit will not apply to constructs within the given instance.

\{AI95-00224-01\} A pragma Suppress gives permission to an implementation to omit the named check (or every check in the case of All_Checks) for any entities to which it applies, from the place of the pragma to the end of the innermost enclosing declarative region, or, if the pragma is given in a package_specification and includes a name, to the end of the scope of the named entity. If the pragma includes a name, the permission applies only to checks performed on the named entity, or, for a subtype, on objects and values of its type. Otherwise, the permission applies to all entities. If permission has been given to suppress a given check, the check is said to be suppressed.

Ramification: A check is suppressed even if the implementation chooses not to actually generate better code. This allows the implementation to raise Program_Error, for example, if the erroneousness is detected.

\{AI95-00224-01\} A pragma Unsuppress revokes the permission to omit the named check (or every check in the case of All_Checks) given by any pragma Suppress that applies at the point of the pragma Unsuppress. The permission is revoked for the region to which the pragma Unsuppress applies. If there is no such permission at the point of a pragma Unsuppress, then the pragma has no effect. A later pragma Suppress can renew the permission.

The following are the language-defined checks:

- [The following checks correspond to situations in which the exception Constraint_Error is raised upon failure.]

  \{8652/0036\} \{AI95-00176-01\} \{AI95-00231-01\} Access_Check
  [When evaluating a dereference (explicit or implicit), check that the value of the name is not \texttt{null}. When converting to a subtype that excludes \texttt{null}, check that the converted value is not \texttt{null}. When passing an actual parameter to a formal access parameter, check that the value of the actual parameter is not \texttt{null}. When evaluating a discriminant_association for an access discriminant, check that the value of the discriminant is not \texttt{null}.]

  Discriminant_Check
  [Check that the discriminants of a composite value have the values imposed by a discriminant constraint. Also, when accessing a record component, check that it exists for the current discriminant values.]

  \{AI95-00434-01\} Division_Check
  [Check that the second operand is not zero for the operations $/$, \texttt{remrem} and \texttt{modmod}.]
Index_Check
[Check that the bounds of an array value are equal to the corresponding bounds of an
index constraint. Also, when accessing a component of an array object, check for each
dimension that the given index value belongs to the range defined by the bounds of the
array object. Also, when accessing a slice of an array object, check that the given discrete
range is compatible with the range defined by the bounds of the array object.]

Length_Check
[Check that two arrays have matching components, in the case of array subtype
conversions, and logical operators for arrays of boolean components.]

Overflow_Check
[Check that a scalar value is within the base range of its type, in cases where the
implementation chooses to raise an exception instead of returning the correct
mathematical result.]

Range_Check
[Check that a scalar value satisfies a range constraint. Also, for the elaboration of a
subtype_indication, check that the constraint (if present) is compatible with the subtype
denoted by the subtype_mark. Also, for an aggregate, check that an index or
discriminant value belongs to the corresponding subtype. Also, check that when the result
of an operation yields an array, the value of each component belongs to the component
subtype.]

Tag_Check
[Check that operand tags in a dispatching call are all equal. Check for the correct tag on
tagged type conversions, for an assignment_statement, and when returning a tagged
limited object from a function.]

• [The following checks correspond to situations in which the exception Program_Error is raised
upon failure.]

{AI95-00280} Accessibility_Check
[Check the accessibility level of an entity or view.]

{AI95-00280} Allocation_Check
[For an allocator, check that the master of any tasks to be created by the allocator is not
yet completed or some dependents have not yet terminated, and that the finalization of
the collection has not started.]

Elaboration_Check
[When a subprogram or protected entry is called, a task activation is accomplished, or a
generic instantiation is elaborated, check that the body of the corresponding unit has
already been elaborated.]

This paragraph was deleted. {AI95-00280} Accessibility_Check
[Check the accessibility level of an entity or view.]

• [The following check corresponds to situations in which the exception Storage_Error is raised
upon failure.]

Storage_Check
[Check that evaluation of an allocator does not require more space than is available for a
storage pool. Check that the space available for a task or subprogram has not been
exceeded.]

Reason: We considered splitting this out into three categories: Pool_Check (for allocators), Stack_Check (for stack
usage), and Heap_Check (for implicit use of the heap — use of the heap other than through an allocator).
Storage_Check would then represent the union of these three. However, there seems to be no compelling reason to do
this, given that it is not feasible to split Storage_Error.
• [The following check corresponds to all situations in which any predefined exception is raised.]

\{AI05-0290-1\} All_Checks

Represents the union of all checks; suppressing All_Checks suppresses all checks other than those associated with assertions. In addition, an implementation is allowed (but not required) to behave as if a pragma Assertion Policy(Ignore) applies to any region to which pragma Suppress(All_Checks) applies.

**Ramification:** All_Checks includes both language-defined and implementation-defined checks.

**To be honest:** \{AI05-0005-1\} There are additional checks defined in various Specialized Needs Annexes that are not listed here. Nevertheless, they are included in All_Checks and named in a Suppress pragma on implementations that support the relevant annex. Look up “check, language-defined” in the index to find the complete list.

**Discussion:** \{AI05-0290-1\} We don't want to say that assertions are suppressed, because we don't want the potential failure of an assertion to cause erroneous execution (see below). Thus they are excluded from the suppression part of the above rule and then handled with an implicit Ignore policy.

**Erroneous Execution**

If a given check has been suppressed, and the corresponding error situation occurs, the execution of the program is erroneous.

**Implementation Permissions**

\{AI95-00224-01\} An implementation is allowed to place restrictions on checking pragmas, subject only to the requirement that \texttt{pragma Unsuppress} shall allow any check names supported by \texttt{pragma Suppress}. An implementation is allowed to add additional check names, with implementation-defined semantics. When Overflow_Check has been suppressed, an implementation may also suppress an unspecified subset of the Range_Checks.

**Reason:** \{AI95-00224-01\} The permission to restrict is given so the implementation can give an error message when the requested suppression is nonsense, such as suppressing a Range_Check on a task type. It would be verbose and pointless to list all the cases of nonsensical language-defined checks in the standard, and since the list of checks is open-ended, we can't list the restrictions for implementation-defined checks anyway.

**Implementation defined:** Implementation-defined check names.

**Discussion:** For Overflow_Check, the intention is that the implementation will suppress any Range_Checks that are implemented in the same manner as Overflow_Checks (unless they are free).

\{AI95-00224-01\} An implementation may support an additional parameter on \texttt{pragma Unsuppress} similar to the one allowed for \texttt{pragma Suppress} (see J.10). The meaning of such a parameter is implementation-defined.

**Implementation defined:** Existence and meaning of second parameter of \texttt{pragma Unsuppress}.

**Implementation Advice**

The implementation should minimize the code executed for checks that have been suppressed.

**Implementation Advice:** Code executed for checks that have been suppressed should be minimized.

**Implementation Note:** However, if a given check comes for free (for example, the hardware automatically performs the check in parallel with doing useful work) or nearly free (for example, the check is a tiny portion of an expensive run-time system call), the implementation should not bother to suppress the check. Similarly, if the implementation detects the failure at compile time and provides a warning message, there is no need to actually suppress the check.

**NOTES**

3 There is no guarantee that a suppressed check is actually removed; hence a \texttt{pragma Suppress} should be used only for efficiency reasons.

4 \{AI95-00224-01\} It is possible to give both a \texttt{pragma Suppress} and Unsuppress for the same check immediately within the same declarative part. In that case, the last \texttt{pragma} given determines whether or not the check is suppressed. Similarly, it is possible to resuppress a check which has been unsuppressed by giving a \texttt{pragma Suppress} in an inner declarative region.
Examples

Examples of suppressing and unsuppressing checks:

{-AI95-00224-01-}

```
pragma Suppress(Index_Check);
pragma Unsuppress(Overflow_Check, Range_Check);
pragma Suppress(Index_Check, On => Table);
```

Extensions to Ada 83

31.1 A pragma Suppress is allowed as a configuration pragma. A pragma Suppress without a name is allowed in a package_specification.

Additional check names are added. We allow implementations to define their own checks.

Wording Changes from Ada 83

31.c We define the checks in a distributed manner. Therefore, the long list of what checks apply to what is merely a NOTE.

31.d We have removed the detailed rules about what is allowed in a pragma Suppress, and allow implementations to invent their own. The RM83 rules weren't quite right, and such a change is necessary anyway in the presence of implementation-defined checks.

31.e We make it clear that the difference between a Range_Check and an Overflow_Check is fuzzy. This was true in Ada 83, given RM83-11.6, but it was not clear. We considered removing Overflow_Check from the language or making it obsolescent, just as we did for Numeric_Error. However, we kept it for upward compatibility, and because it may be useful on machines where range checking costs more than overflow checking, but overflow checking still costs something. Different compilers will suppress different checks when asked to suppress Overflow_Check — the nonuniformity in this case is not harmful, and removing it would have a serious impact on optimizers.

31.f Under Access_Check, dereferences cover the cases of selected_component, indexed_component, slice, and attribute that are listed in RM83, as well as the new explicit_dereference, which was included in selected_component in RM83.

Extensions to Ada 95

31.g {-AI95-00224-01-} Pragma Unsuppress is new.

31.h {-AI95-00280-01-} Allocation_Check was added to support suppressing the new check on allocators (see 4.8).

Wording Changes from Ada 95

31.i {-8652/0036-} {-AI95-00176-01-} {-AI95-00224-01-} The description of Access_Check was corrected by the Corrigendum to include the discriminant case. This change was then replaced by the more general notion of checking conversions to subtypes that exclude null in Ada 2005.

31.j {-AI95-00224-01-} The On parameter of pragma Suppress was moved to Annex J (see J.10). This feature's effect is inherently nonportable, depending on the implementation's model of computation. Compiler surveys demonstrated this, showing that implementations vary widely in the interpretation of these parameters, even on the same target. While this is relatively harmless for Suppress (which is never required to do anything), it would be a significant problem for Unsuppress (we want the checks to be made for all implementations). By moving it, we avoid needing to define the meaning of Unsuppress with an On parameter.

31.k {-AI95-00280-01-} The order of the Program_Error checks was corrected to be alphabetical.

Wording Changes from Ada 2005

31.l {-AI05-0290-1-} The effect of a checking pragma no longer applies inside an inlined subprogram body. While this could change the behavior of a program that depends on a check being suppressed in an inlined body, such a program is erroneous and thus no behavior can be depended upon anyway. It's also likely to be very rare. We make this change so that inlining has no effect on the meaning of the subprogram body (since inlining is never requiring, this is necessary in order to be able to reason about the body), and so that assertion policies and suppress work the same way for inlining.

11.6 Exceptions and Optimization

{-AI05-0299-1-} [ This subclause gives permission to the implementation to perform certain “optimizations” that do not necessarily preserve the canonical semantics.]
Dynamic Semantics

{AI05-0299-1} The rest of this International Standard (outside this subclause) defines the canonical semantics of the language. [The canonical semantics of a given (legal) program determines a set of possible external effects that can result from the execution of the program with given inputs.]

Ramification: Note that the canonical semantics is a set of possible behaviors, since some reordering, parallelism, and nondeterminism is allowed by the canonical semantics.

Discussion: {AI05-0299-1} The following parts of the canonical semantics are of particular interest to the reader of this subclause:
• Behavior in the presence of abnormal objects and objects with invalid representations (see 13.9.1).
• Various actions that are defined to occur in an arbitrary order.
• {AI05-0299-1} Behavior in the presence of a misuse of Unchecked_Deallocation, Unchecked_Access, or imported or exported entity (see ClauseSection 13).

{AI05-0299-1} [As explained in 1.1.3, “Conformity of an Implementation with the Standard”, the external effect of a program is defined in terms of its interactions with its external environment. Hence, the implementation can perform any internal actions whatsoever, in any order or in parallel, so long as the external effect of the execution of the program is one that is allowed by the canonical semantics, or by the rules of this subclause.]

Ramification: Note that an optimization can change the external effect of the program, so long as the changed external effect is an external effect that is allowed by the semantics. Note that the canonical semantics of an erroneous execution allows any external effect whatsoever. Hence, if the implementation can prove that program execution will be erroneous in certain circumstances, there need not be any constraints on the machine code executed in those circumstances.

Implementation Permissions

The following additional permissions are granted to the implementation:

• An implementation need not always raise an exception when a language-defined check fails. Instead, the operation that failed the check can simply yield an undefined result. The exception need be raised by the implementation only if, in the absence of raising it, the value of this undefined result would have some effect on the external interactions of the program. In determining this, the implementation shall not presume that an undefined result has a value that belongs to its subtype, nor even to the base range of its type, if scalar. [Having removed the raise of the exception, the canonical semantics will in general allow the implementation to omit the code for the check, and some or all of the operation itself.]

Ramification: Even without this permission, an implementation can always remove a check if it cannot possibly fail.

Reason: We express the permission in terms of removing the raise, rather than the operation or the check, as it minimizes the disturbance to the canonical semantics (thereby simplifying reasoning). By allowing the implementation to omit the raise, it thereby does not need to "look" at what happens in the exception handler to decide whether the optimization is allowed.

Discussion: The implementation can also omit checks if they cannot possibly fail, or if they could only fail in erroneous executions. This follows from the canonical semantics.

Implementation Note: This permission is intended to allow normal "dead code removal" optimizations, even if some of the removed code might have failed some language-defined check. However, one may not eliminate the raise of an exception if subsequent code presumes in some way that the check succeeded. For example:

\[
\text{if } X \times Y > \text{Integer'Last then}
\text{Put_Line("X \times Y overflowed");}
\text{end if;}
\text{exception}
\text{when others =>}
\text{Put_Line("X \times Y overflowed");}
\]

If \(X \times Y\) does overflow, you may not remove the raise of the exception if the code that does the comparison against \text{Integer'Last} presumes that it is comparing it with an in-range Integer value, and hence always yields False.

As another example where a raise may not be eliminated:

5.9

```ada
subtype Str10 is String(1..10);
type P10 is access Str10;
X : P10 := null;
begin
  if X.all'Last = 10 then
    Put_Line("Oops");
  end if;
```

In the above code, it would be wrong to eliminate the raise of Constraint_Error on the "X.all" (since X is null), if the code to evaluate 'Last always yields 10 by presuming that X.all belongs to the subtype Str10, without even "looking."

6/3

- \{AI05-0229-1\} If an exception is raised due to the failure of a language-defined check, then upon reaching the corresponding exception_handler (or the termination of the task, if none), the external interactions that have occurred need reflect only that the exception was raised somewhere within the execution of the sequence_of_statements with the handler (or the task_body), possibly earlier (or later if the interactions are independent of the result of the checked operation) than that defined by the canonical semantics, but not within the execution of some abort-deferred operation or independent subprogram that does not dynamically enclose the execution of the construct whose check failed. An independent subprogram is one that is defined outside the library unit containing the construct whose check failed, and for which the_subprogram Inline aspect is FalsePragma applied to it. Any assignment that occurred outside of such abort-deferred operations or independent subprograms can be disrupted by the raising of the exception, causing the object or its parts to become abnormal, and certain subsequent uses of the object to be erroneous, as explained in 13.9.1.

6.a

**Reason:** We allow such variables to become abnormal so that assignments (other than to atomic variables) can be disrupted due to “imprecise” exceptions or instruction scheduling, and so that assignments can be reordered so long as the correct results are produced in the end if no language-defined checks fail.

6.b

**Ramification:** If a check fails, no result dependent on the check may be incorporated in an external interaction. In other words, there is no permission to output meaningless results due to postponing a check.

6.c

**Discussion:** We believe it is important to state the extra permission to reorder actions in terms of what the programmer can expect at run time, rather than in terms of what the implementation can assume, or what transformations the implementation can perform. Otherwise, how can the programmer write reliable programs?

6.d/3

- \{AI05-0299-1\} This subclause has two conflicting goals: to allow as much optimization as possible, and to make program execution as predictable as possible (to ease the writing of reliable programs). The rules given above represent a compromise.

6.e

Consider the two extremes:

6.f/3

- \{AI05-0299-1\} The extreme conservative rule would be to delete this subclause entirely. The semantics of Ada would be the canonical semantics. This achieves the best predictability. It sounds like a disaster from the efficiency point of view, but in practice, implementations would provide modes in which less predictability but more efficiency would be achieved. Such a mode could even be the out-of-the-box mode. In practice, implementers would provide a compromise based on their customer's needs. Therefore, we view this as one viable alternative.

6.g

The extreme liberal rule would be “the language does not specify the execution of a program once a language-defined check has failed; such execution can be unpredictable.” This achieves the best efficiency. It sounds like a disaster from the predictability point of view, but in practice it might not be so bad. A user would have to assume that exception handlers for exceptions raised by language-defined checks are not portable. They would have to isolate such code (like all nonportable code), and would have to find out, for each implementation of interest, what behaviors can be expected. In practice, implementations would tend to avoid going so far as to punish their customers too much in terms of predictability.

6.h/3

- \{AI05-0299-1\} The most important thing about this subclause is that users understand what they can expect at run time, and implementers understand what optimizations are allowed. Any solution that makes this subclause contain rules that can interpreted in more than one way is unacceptable.

6.i

We have chosen a compromise between the extreme conservative and extreme liberal rules. The current rule essentially allows arbitrary optimizations within a library unit and inlined subprograms reachable from it, but disallow semantics-disrupting optimizations across library units in the absence of inlined subprograms. This allows a library unit to be debugged, and then reused with some confidence that the abstraction it manages cannot be broken by bugs outside the library unit.

**NOTES**

5 \{AI05-0299-1\} The permissions granted by this subclause can have an effect on the semantics of a program only if the program fails a language-defined check.

11.6 Exceptions and Optimization 13 December 2012 498
RM83-11.6 was unclear. It has been completely rewritten here; we hope this version is clearer. Here's what happened to each paragraph of RM83-11.6:

- Paragraphs 1 and 2 contain no semantics; they are merely pointing out that anything goes if the canonical semantics is preserved. We have similar introductory paragraphs, but we have tried to clarify that these are not granting any “extra” permission beyond what the rest of the document allows.

- Paragraphs 3 and 4 are reflected in the “extra permission to reorder actions”. Note that this permission now allows the reordering of assignments in many cases.

- Paragraph 5 is moved to 4.5, “Operators and Expression Evaluation”, where operator association is discussed. Hence, this is no longer an “extra permission” but is part of the canonical semantics.

- Paragraph 6 now follows from the general permission to store out-of-range values for unconstrained subtypes. Note that the parameters and results of all the predefined operators of a type are of the unconstrained subtype of the type.

- Paragraph 7 is reflected in the “extra permission to avoid raising exceptions”.

\{AI05-0299-1\} We moved subclause 11.5, “Suppressing Checks” from after 11.6 to before 11.6, in order to preserve the famous number “11.6” (given the changes to earlier subclauses in Clause Section 11).
12 Generic Units

A generic unit is a program unit that is either a generic subprogram or a generic package. A generic unit is a template, which can be parameterized, and from which corresponding (nongeneric) subprograms or packages can be obtained. The resulting program units are said to be instances of the original generic unit.

**Glossary entry:** A generic unit is a template for a (nongeneric) program unit; the template can be parameterized by objects, types, subprograms, and packages. An instance of a generic unit is created by a generic instantiation. The rules of the language are enforced when a generic unit is compiled, using a generic contract model; additional checks are performed upon instantiation to verify the contract is met. That is, the declaration of a generic unit represents a contract between the body of the generic and instances of the generic. Generic units can be used to perform the role that macros sometimes play in other languages.

A generic unit is declared by a generic_declaration. This form of declaration has a generic_formal_part declaring any generic formal parameters. An instance of a generic unit is obtained as the result of a generic_instantiation with appropriate generic actual parameters for the generic formal parameters. An instance of a generic subprogram is a subprogram. An instance of a generic package is a package.

Generic units are templates. As templates they do not have the properties that are specific to their nongeneric counterparts. For example, a generic subprogram can be instantiated but it cannot be called. In contrast, an instance of a generic subprogram is a (nongeneric) subprogram; hence, this instance can be called but it cannot be used to produce further instances.

12.1 Generic Declarations

A generic_declaration declares a generic unit, which is either a generic subprogram or a generic package. A generic_declaration includes a generic_formal_part declaring any generic formal parameters. A generic formal parameter can be an object; alternatively (unlike a parameter of a subprogram), it can be a type, a subprogram, or a package.

**Syntax**

\[
\text{generic} \quad \text{declaration} \quad ::= \quad \text{generic} \quad \text{subprogram} \quad \text{declaration} \quad | \quad \text{generic} \quad \text{package} \quad \text{declaration} \\
\quad \{\text{AI05-0183-1}\} \quad \text{generic} \quad \text{subprogram} \quad \text{declaration} \quad ::= \\
\quad \quad \quad \text{generic} \quad \text{formal} \quad \text{part} \quad \text{subprogram} \quad \text{specification} \quad | \quad \text{aspect} \quad \text{specification} \\
\quad \text{generic} \quad \text{package} \quad \text{declaration} \quad ::= \\
\quad \quad \quad \text{generic} \quad \text{formal} \quad \text{part} \quad \text{package} \quad \text{specification} \\
\quad \quad \quad \text{Ramification:} \quad \{\text{AI05-0183-1}\} \quad \text{No syntax change is needed here to allow an aspect specification; a generic package can have an aspect specification because a package specification allows an aspect specification.} \\
\quad \text{generic} \quad \text{formal} \quad \text{part} \quad ::= \quad \text{generic} \quad \{\text{generic} \quad \text{formal} \quad \text{parameter} \quad \text{declaration} \quad | \quad \text{use} \quad \text{clause}\} \\
\quad \text{generic} \quad \text{formal} \quad \text{parameter} \quad \text{declaration} \quad ::= \\
\quad \quad \quad \text{formal} \quad \text{object} \quad \text{declaration} \quad | \quad \text{formal} \quad \text{type} \quad \text{declaration} \quad | \quad \text{formal} \quad \text{subprogram} \quad \text{declaration} \quad | \quad \text{formal} \quad \text{package} \quad \text{declaration} \\
\quad \text{The only form of subtype indication allowed within a generic formal part is a subtype mark} \quad [(\text{that is, the subtype indication shall not include an explicit constraint})]. \quad \text{The defining name of a generic subprogram shall be an identifier } [(\text{not an operator symbol})].
\]
Reason: The reason for forbidding constraints in subtype indications is that it simplifies the elaboration of generic declarations (since there is nothing to evaluate), and that it simplifies the matching rules, and makes them more checkable at compile time.

Static Semantics

{AI95-00434-01} A generic declaration declares a generic unit — a generic package, generic procedure, or generic function, as appropriate.

An entity is a generic formal entity if it is declared by a generic formal parameter declaration. “Generic formal,” or simply “formal,” is used as a prefix in referring to objects, subtypes (and types), functions, procedures and packages, that are generic formal entities, as well as to their respective declarations. [Examples: “generic formal procedure” or a “formal integer type declaration.”]

Dynamic Semantics

The elaboration of a generic declaration has no effect.

NOTES

1 Outside a generic unit a name that denotes the generic declaration denotes the generic unit. In contrast, within the declarative region of the generic unit, a name that denotes the generic declaration denotes the current instance.

Proof: This is stated officially as part of the “current instance” rule in 8.6, “The Context of Overload Resolution”. See also 12.3, “Generic Instantiation”.

2 Within a generic subprogram body, the name of this program unit acts as the name of a subprogram. Hence this name can be overloaded, and it can appear in a recursive call of the current instance. For the same reason, this name cannot appear after the reserved word new in a (recursive) generic instantiation.

3 A default_expression or default_name appearing in a generic formal part is not evaluated during elaboration of the generic formal part; instead, it is evaluated when used. (The usual visibility rules apply to any name used in a default: the denoted declaration therefore has to be visible at the place of the expression.)

Examples of generic formal parts:

generic -- parameterless

generic
Size : Natural;  -- formal object

generic
Length : Integer := 200;          -- formal object with a default expression
Area   : Integer := Length*Length; -- formal object with a default expression

generic

type Item is private;    -- formal type

type Index is (<>);     -- formal type

type Row is array(Index range <>) of Item; -- formal type

with function "<"(X, Y : Item) return Boolean; -- formal subprogram

Examples of generic declarations declaring generic subprograms Exchange and Squaring:

generic

procedure Exchange(U, V : in out Elem);

generic

with function "**"(U, V : Item) return Item is <>;
function Squaring(X : Item) return Item;
Example of a generic declaration declaring a generic package:

```ada
generic
    type Item is private;
    type Vector is array (Positive range <>) of Item;
    with function Sum(X, Y : Item) return Item;
package On_Vectors is
    function Sum (A, B : Vector) return Vector;
    function Sigma(A : Vector) return Item;
    Length_Error : exception;
end On_Vectors;
```

Extensions to Ada 83

The syntax rule for `generic_formal_parameter_declaration` is modified to allow the reserved words `tagged` and `abstract`, to allow formal derived types, and to allow formal packages.

Use clauses are allowed in `generic_formal_part`. This is necessary in order to allow a use clause within a formal part to provide direct visibility of declarations within a generic formal package.

Wording Changes from Ada 83

{AI05-0299-1} The syntax for `generic_formal_parameter_declaration` and `formal_type_definition` is split up into more named categories. The rules for these categories are moved to the appropriate clauses and subclauses. The names of the categories are changed to be more intuitive and uniform. For example, we changed `generic_parameter_declaration` to `generic_formal_parameter_declaration`, because the thing it declares is a generic formal, not a generic. In the others, we abbreviate “generic formal” to just “formal”. We can't do that for `generic_formal_parameter_declaration`, because of confusion with normal formal parameters of subprograms.

Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in a `generic_subprogram_declaration` (as well as a `generic_package_declaration`). This is described in 13.1.1.

### 12.2 Generic Bodies

The body of a generic unit (a `generic body`) [is a template for the instance bodies. The syntax of a generic body is identical to that of a nongeneric body].

**Ramification:** We also use terms like “generic function body” and “nongeneric package body.”

**Dynamic Semantics**

The elaboration of a generic body has no other effect than to establish that the generic unit can from then on be instantiated without failing the Elaboration_Check. If the generic body is a child of a generic package, then its elaboration establishes that each corresponding declaration nested in an instance of the parent (see 10.1.1) can from then on be instantiated without failing the Elaboration_Check.

**NOTES**

4 The syntax of generic subprograms implies that a generic subprogram body is always the completion of a declaration.

**Examples**

Example of a generic procedure body:

```ada
procedure Exchange(U, V : in out Elem) is -- see 12.1
    T : Elem; -- the generic formal type
begin
    T := U;
    U := V;
    V := T;
end Exchange;
```
Example of a generic function body:

```ada
function Squaring(X : Item) return Item is -- see 12.1
begin
    return X*X;  -- the formal operator "**"
end Squaring;
```

Example of a generic package body:

```ada
package body On_Vectors is -- see 12.1

function Sum(A, B : Vector) return Vector is
    Result : Vector(A'Range); -- the formal type Vector
    Bias   : constant Integer := B'First - A'First;
begin
    if A'Length /= B'Length then
        raise Length_Error;
    end if;
    for N in A'Range loop
        Result(N) := Sum(A(N), B(N + Bias)); -- the formal function Sum
    end loop;
    return Result;
end Sum;

function Sigma(A : Vector) return Item is
    Total : Item := A(A'First); -- the formal type Item
begin
    for N in A'First + 1 .. A'Last loop
        Total := Sum(Total, A(N)); -- the formal function Sum
    end loop;
    return Total;
end Sigma;
end On_Vectors;
```

### 12.3 Generic Instantiation

[An instance of a generic unit is declared by a generic_instantiation.]

#### Language Design Principles

1.a/3

The legality of an instance should be determinable without looking at the generic body. Likewise, the legality of a generic body should be determinable without looking at any instances. Thus, the generic_declaration forms a contract between the body and the instances; if each obeys the rules with respect to the generic_declaration, then no legality problems will arise. This is really a special case of the “legality determinable via semantic dependences” Language Design Principle (see ClauseSection 10), given that a generic_instantiation does not depend semantically upon the generic body, nor vice-versa.

1.b

Run-time issues are another story. For example, whether parameter passing is by copy or by reference is determined in part by the properties of the generic actuals, and thus cannot be determined at compile time of the generic body. Similarly, the contract model does not apply to Post-Compilation Rules.
Syntax

{AI95-00218-03} {AI05-0183-1} generic_instantiation ::=  
  package defining_program_unit_name is 
  new generic_package_name [generic_actual_part] 
    [aspect_specification];
  | [overriding_indicator]  
  procedure defining_program_unit_name is 
  new generic_procedure_name [generic_actual_part] 
    [aspect_specification];
  | [overriding_indicator]  
  function defining_designator is 
  new generic_function_name [generic_actual_part] 
    [aspect_specification];

generic_actual_part ::=  
  (generic_association {, generic_association})

generic_association ::=  
  [generic_formal_parameter_selector_name =>] explicit_generic_actual_parameter

explicit_generic_actual_parameter ::= expression | variable_name
  | subprogram_name | entry_name | subtype_mark
  | package_instance_name

A generic_association is named or positional according to whether or not the generic_formal_parameter_selector_name is specified. Any positional associations shall precede any named associations.

{AI05-0004-1} The generic actual parameter is either the explicit_generic_actual_parameter given in a generic_association for each formal, or the corresponding default_expression or default_name if no generic_association is given for the formal. When the meaning is clear from context, the term “generic actual,” or simply “actual,” is used as a synonym for “generic actual parameter” and also for the view denoted by one, or the value of one.

Legality Rules

In a generic_instantiation for a particular kind of program unit [(package, procedure, or function)], the name shall denote a generic unit of the corresponding kind [(generic package, generic procedure, or generic function, respectively)].

{AI05-0118-1} The generic_formal_parameter_selector_name of a named generic_association shall denote a generic_formal_parameter_declaration of the generic unit being instantiated. If two or more formal subprograms have the same defining name, then named associations are not allowed for the corresponding actuals.

{AI05-0118-1} The generic_formal_parameter_declaration for a positional generic_association is the parameter with the corresponding position in the generic_formal_part of the generic unit being instantiated.

A generic_instantiation shall contain at most one generic_association for each formal. Each formal without an association shall have a default_expression or subprogram_default.

In a generic unit Legality Rules are enforced at compile time of the generic_declaration and generic body, given the properties of the formals. In the visible part and formal part of an instance, Legality Rules are enforced at compile time of the generic_instantiation, given the properties of the actuals. In other parts of an instance, Legality Rules are not enforced; this rule does not apply when a given rule explicitly specifies otherwise.
Reason: \{AI95-00114-01\} Since rules are checked using the properties of the formals, and since these properties do not always carry over to the actuals, we need to check the rules again in the visible part of the instance. For example, only if a tagged type is limited may an extension of it have limited components in the instance body. A formal tagged limited type is limited, but the actual might be nonlimited. Hence any rule that requires a tagged type to be limited runs into this problem. Such rules are rare; in most cases, the rules for matching of formals and actuals guarantee that if the rule is obeyed in the generic unit, then it has to be obeyed in the instance.

\{AI05-0005-1\} Ada 2012 addendum: Such Legality Rules are not as rare as the authors of Ada 95 hoped; there are more than 30 of them known at this point. They are indexed under "generic contract issue" and are associated with the boilerplate "In addition to the places where Legality Rules normally apply...". Indeed, there is only one known rule where rechecking in the specification is needed and where rechecking in the private part is not wanted (it is in 3.4, but even it needs rechecking when tagged types are involved).

Ramification: The "properties" of the formals are determined without knowing anything about the actuals:

- \{AI95-00034-01\} A formal derived subtype is constrained if and only if the ancestor subtype is constrained. A formal array type is constrained if and only if the declarations say so. A formal private type is constrained if it does not have a discriminant part. Other formal subtypes are unconstrained, even though they might be constrained in an instance.

- A formal subtype can be indefinite, even though the copy might be definite in an instance.

- A formal object of mode in is not a static constant; in an instance, the copy is static if the actual is.

- A formal subtype is not static, even though the actual might be.

- Formal types are specific, even though the actual can be class-wide.

- The subtype of a formal object of mode in out is not static. (This covers the case of AI83-00878.)

- The subtype of a formal parameter of a formal subprogram does not provide an applicable index constraint.

- The profile of a formal subprogram is not subtype conformant with any other profile.

- A generic formal function is not static.

Ramification: The exceptions to the above rule about when legality rules are enforced fall into these categories:

- Some rules are checked in the generic declaration, and then again in both the visible and private parts of the instance:

  - The parent type of a record extension has to be specific (see 3.9.1). This rule is not checked in the instance body.

  - The parent type of a private extension has to be specific (see 7.3). This rule is not checked in the instance body.

- \{AI95-00402-01\} \{AI05-0093-1\} A type with an access discriminant with a default_expression has to be immutably limited. In the generic body, the definition of immutably limited is adjusted in an assume-the-worst manner (thus the rule is checked that way). A descendant of an explicitly limited record type declared with limited, or be a task or protected type. This rule is irrelevant in the instance body.

- In the declaration of a record extension, if the parent type is nonlimited, then each of the components of the record_extension_part have to be nonlimited (see 3.9.1). In the generic body, this rule is checked in an assume-the-worst manner.

- A preelaborated library unit has to be preelaborable (see 10.2.1). In the generic body, this rule is checked in an assume-the-worst manner.

- The corrections made by the Corrigendum added a number of such rules, and the Amendment added many more. There doesn't seem to be much value in repeating all of these rules here (as of this writing, there are roughly 33 such rules). As noted below, all such rules are indexed in the AARM.

- For the accessibility rules, the formals have nothing to say about the property in question. Like the above rules, these rules are checked in the generic declaration, and then again in both the visible and private parts of the instance. In the generic body, we have explicit rules that essentially assume the worst (in the cases of type extensions and access-to-subprogram types), and we have run-time checks (in the case of access-to-object types). See 3.9.1, 3.10.2, and 4.6.

  We considered run-time checks for access-to-subprogram types as well. However, this would present difficulties for implementations that share generic bodies.

- The rules requiring "reasonable" values for static expressions are ignored when the expected type for the expression is a descendant of a generic formal type other than a generic formal derived type, and do not apply in an instance.
• The rule forbidding two explicit homographs in the same declarative region does not apply in an instance of a generic unit, except that it does apply in the declaration of a record extension that appears in the visible part of an instance.

• Some rules do not apply at all in an instance, not even in the visible part:
  • Body_stubs are not normally allowed to be multiply nested, but they can be in instances.

Each rule that is an exception is marked with “generic contract issue;” look that up in the index to find them all.

Ramification: The Legality Rules are the ones labeled Legality Rules. We are talking about all Legality Rules in the entire language here. Note that, with some exceptions, the legality of a generic unit is checked even if there are no instantiations of the generic unit.

Ramification: {A05-0299-1} The Legality Rules are described here, and the overloading rules were described earlier in this subclause. Presumably, every Static Semantic Item is sucked in by one of those. Thus, we have covered all the compile-time rules of the language. There is no need to say anything special about the Post-Compilation Rules or the Dynamic Semantic Items.

Discussion: Here is an example illustrating how this rule is checked: “In the declaration of a record extension, if the parent type is nonlimited, then each of the components of the record_extension_part shall be nonlimited.”

```ada
generic
  type Parent is tagged private;
  type Comp is limited private;
package G1 is
  type Extension is new Parent with
    record
    C : Comp; -- Illegal!
  end record;
end G1;
```

The parent type is nonlimited, and the component type is limited, which is illegal. It doesn't matter that one could imagine writing an instantiation with the actual for Comp being nonlimited — we never get to the instance, because the generic itself is illegal.

On the other hand:

```ada
generic
  type Parent is tagged limited private; -- Parent is limited.
  type Comp is limited private;
package G2 is
  type Extension is new Parent with
    record
    C : Comp; -- OK.
  end record;
end G2;
```

```ada
type Limited_Tagged is tagged limited null record;
type Non_Limited_Tagged is tagged null record;
type Limited_Untagged is limited null record;
type Non_Limited_Untagged is null record;
package Good_1 is new G2(Parent => Limited_Tagged, Comp => Limited_Untagged);
package Good_2 is new G2(Parent => Non_Limited_Tagged, Comp => Non_Limited_Untagged);
package Bad is new G2(Parent => Non_Limited_Tagged, Comp => Limited_Untagged); -- Illegal!
```

The first instantiation is legal, because in the instance the parent is limited, so the rule is not violated. Likewise, in the second instantiation, the rule is not violated in the instance. However, in the Bad instance, the parent type is nonlimited, and the component type is limited, so this instantiation is illegal.

**Static Semantics**

A generic_instantiation declares an instance; it is equivalent to the instance declaration (a package_declaration or subprogram_declaration) immediately followed by the instance body, both at the place of the instantiation.

**Ramification:** The declaration and the body of the instance are not “implicit” in the technical sense, even though you can't see them in the program text. Nor are declarations within an instance “implicit” (unless they are implicit by other rules). This is necessary because implicit declarations have special semantics that should not be attached to instances. For a generic subprogram, the profile of a generic_instantiation is that of the instance declaration, by the stated equivalence.
12.b **Ramification:** The visible and private parts of a package instance are defined in 7.1, “Package Specifications and Declarations” and 12.7, “Formal Packages”. The visible and private parts of a subprogram instance are defined in 8.2, “Scope of Declarations”.

13 The instance is a copy of the text of the template. [Each use of a formal parameter becomes (in the copy) a use of the actual, as explained below.] An instance of a generic package is a package, that of a generic procedure is a procedure, and that of a generic function is a function.

13.a **Ramification:** An instance is a package or subprogram (because we say so), even though it contains a copy of the generic formal part, and therefore doesn't look like one. This is strange, but it's OK, since the syntax rules are overloading rules, and therefore do not apply in an instance.

13.b **Discussion:** We use a macro-expansion model, with some explicitly-stated exceptions (see below). The main exception is that the interpretation of each construct in a generic unit (especially including the denotation of each name) is determined when the declaration and body of the generic unit (as opposed to the instance) are compiled, and in each instance this interpretation is (a copy of) the template interpretation. In other words, if a construct is interpreted as a name denoting a declaration D, then in an instance, the copy of the construct will still be a name, and will still denote D (or a copy of D). From an implementation point of view, overload resolution is performed on the template, and not on each copy.

13.c We describe the substitution of generic actual parameters by saying (in most cases) that the copy of each generic formal parameter declares a view of the actual. Suppose a name in a generic unit denotes a generic_formal_parameter_declaration. The copy of that name in an instance will denote the copy of that generic_formal_parameter_declaration in the instance. Since the generic_formal_parameter_declaration in the instance declares a view of the actual, the name will denote a view of the actual.

13.d/2 [AI95-00442-01] Other properties of the copy (for example, staticness, categories, to which types belong) are recalculated for each instance; this is implied by the fact that it's a copy.

13.e/2 [AI95-00317-01] Although the generic_formal_part is included in an instance, the declarations in the generic_formal_part are only visible outside the instance in the case of a generic formal package whose formal_package_actual_part includes one or more <> indicators — see 12.7.

14 The interpretation of each construct within a generic declaration or body is determined using the overloading rules when that generic declaration or body is compiled. In an instance, the interpretation of each (copied) construct is the same, except in the case of a name that denotes the generic_declaration or some declaration within the generic unit; the corresponding name in the instance then denotes the corresponding copy of the denoted declaration. The overloading rules do not apply in the instance.

14.a **Ramification:** See 8.6, “The Context of Overload Resolution” for definitions of “interpretation” and “overloading rule.”

14.b Even the generic_formal_parameter_declarations have corresponding declarations in the instance, which declare views of the actuals.

14.c Although the declarations in the instance are copies of those in the generic unit, they often have quite different properties, as explained below. For example a constant declaration in the generic unit might declare a nonstatic constant, whereas the copy of that declaration might declare a static constant. This can happen when the staticness depends on some generic formal.

14.d This rule is partly a ramification of the “current instance” rule in 8.6, “The Context of Overload Resolution”. Note that that rule doesn't cover the generic_formal_part.

14.e Although the overloading rules are not observed in the instance, they are, of course, observed in the _instantiation in order to determine the interpretation of the constituents of the _instantiation.

14.f Since children are considered to occur within their parent's declarative region, the above rule applies to a name that denotes a child of a generic unit, or a declaration inside such a child.

14.g Since the Syntax Rules are overloading rules, it is possible (legal) to violate them in an instance. For example, it is possible for an instance body to occur in a package_specification, even though the Syntax Rules forbid bodies in package_specifications.

15 In an instance, a generic_formal_parameter_declaration declares a view whose properties are identical to those of the actual, except as specified in 12.4, “Formal Objects” and 12.6, “Formal Subprograms”. Similarly, for a declaration within a generic_formal_parameter_declaration, the corresponding declaration in an instance declares a view whose properties are identical to the corresponding declaration within the declaration of the actual.
Ramification: In an instance, there are no “properties” of types and subtypes that come from the formal. The primitive operations of the type come from the formal, but these are declarations in their own right, and are therefore handled separately.

Note that certain properties that come from the actuals are irrelevant in the instance. For example, if an actual type is of a class deeper in the derived-type hierarchy than the formal, it is impossible to call the additional operations of the deeper class in the instance, because any such call would have to be a copy of some corresponding call in the generic unit, which would have been illegal. However, it is sometimes possible to reach into the specification of the instance from outside, and notice such properties. For example, one could pass an object declared in the instance specification to one of the additional operations of the deeper type.

A formal_type_declaration can contain discriminant_specifications, a formal_subprogram_declaration can contain parameter_specifications and formal_parameter_specifications, and a formal_package_declaration can contain many kinds of declarations. These are all inside the generic unit, and have corresponding declarations in the instance.

This rule implies, for example, that if a subtype in a generic unit is a subtype of a generic formal subtype, then the corresponding subtype in the instance is a subtype of the corresponding actual subtype.

For a generic_instantiation, if a generic actual is a static [(scalar or string)] subtype, then each use of the corresponding formal parameter within the specification of the instance is considered to be static. (See AI83-00409.) Similarly, if a generic actual is a static expression and the corresponding formal parameter has a static [(scalar or string)] subtype, then each use of the formal parameter in the specification of the instance is considered to be static. (See AI83-00505.)

If a primitive subprogram of a type derived from a generic formal derived tagged type is not overriding (that is, it is a new subprogram), it is possible for the copy of that subprogram in an instance to override a subprogram inherited from the actual. For example:

```ada
generic
  type T1 is tagged record ... end record;

package G is
  type Derived_From_Formal is new T1;
  procedure Foo(X : Derived_From_Formal); -- Does not override anything;
end G;

type T2 is new T1 with record ... end record;
procedure Foo(X : T2);

package Inst is new G(Formal => T2);
```

In the instance Inst, the declaration of Foo for Derived_From_Formal overrides the Foo inherited from T2.

Implementation Note: {8652/0009} AI95-00137-01 For formal types, an implementation that shares the code among multiple instances of the same generic unit needs to beware that things like parameter passing mechanisms (by-copy vs. by-reference) and aspect_clause_representation_clause are determined by the actual.

Implicit declarations are also copied, and a name that denotes an implicit declaration in the generic denotes the corresponding copy in the instance. However, for a type declared within the visible part of the generic, a whole new set of primitive subprograms is implicitly declared for use outside the instance, and may differ from the copied set if the properties of the type in some way depend on the properties of some actual type specified in the instantiation. For example, if the type in the generic is derived from a formal private type, then in the instance the type will inherit subprograms from the corresponding actual type. These new implicit declarations occur immediately after the type declaration in the instance, and override the copied ones. The copied ones can be called only from within the instance; the new ones can be called only from outside the instance, although for tagged types, the body of a new one can be executed by a call to an old one.

Proof: This rule is stated officially in 8.3, “Visibility”.

Ramification: The new ones follow from the class(es) of the formal types. For example, for a type T derived from a generic formal private type, if the actual is Integer, then the copy of T in the instance has a "+=" primitive operator, which can be called from outside the instance (assuming T is declared in the visible part of the instance).

AI83-00398.

AI95-00442-01} Since an actual type is always in the category_class determined for the formal, the new subprograms hide all of the copied ones, except for a declaration of "/=" that corresponds to an explicit declaration of "+=“. Such "+=" operators are special, because unlike other implicit declarations of primitive subprograms, they do not appear by virtue
of the class, but because of an explicit declaration of "=". If the declaration of "=" is implicit (and therefore overridden
in the instance), then a corresponding implicitly declared "/=" is also overridden. But if the declaration of "=" is
explicit (and therefore not overridden in the instance), then a corresponding implicitly declared "/=" is not overridden
either, even though it's implicit.

Note that the copied ones can be called from inside the instance, even though they are hidden from all visibility,
because the names are resolved in the generic unit — visibility is irrelevant for calls in the instance.

[In the visible part of an instance, an explicit declaration overrides an implicit declaration if they are
homographs, as described in 8.3.] On the other hand, an explicit declaration in the private part of an
instance overrides an implicit declaration in the instance, only if the corresponding explicit declaration in
the generic overrides a corresponding implicit declaration in the generic. Corresponding rules apply to the
other kinds of overriding described in 8.3.

**Ramification:** For example:

```ada
type Ancestor is tagged null record;

generic
    type Formal is new Ancestor with private;
package G is
    type T is new Formal with null record;
    procedure P(X : in T); -- (1)
private
    procedure Q(X : in T); -- (2)
end G;

type Actual is new Ancestor with null record;
procedure P(X : in Actual);
procedure Q(X : in Actual);

package Instance is new G(Formal => Actual);
```

In the instance, the copy of P at (1) overrides Actual's P, whereas the copy of Q at (2) does not override anything; in
implementation terms, it occupies a separate slot in the type descriptor.

**Reason:** The reason for this rule is so a programmer writing an _instantiation need not look at the private part of the
generic in order to determine which subprograms will be overridden.

**Post-Compilation Rules**

Recursive generic instantiation is not allowed in the following sense: if a given generic unit includes an
instantiation of a second generic unit, then the instance generated by this instantiation shall not include an
instance of the first generic unit [(whether this instance is generated directly, or indirectly by intermediate
instantiations)].

**Discussion:** Note that this rule is not a violation of the generic contract model, because it is not a Legality Rule. Some
implementations may be able to check this rule at compile time, but that requires access to all the bodies, so we allow
implementations to check the rule at link time.

**Dynamic Semantics**

For the elaboration of a generic_instantiation, each generic_association is first evaluated. If a default is
used, an implicit generic_association is assumed for this rule. These evaluations are done in an arbitrary
order, except that the evaluation for a default actual takes place after the evaluation for another actual if
the default includes a name that denotes the other one. Finally, the instance declaration and body are
elaborated.

**Ramification:** Note that if the evaluation of a default depends on some side effect of some other evaluation, the order
is still arbitrary.

For the evaluation of a generic_association the generic actual parameter is evaluated. Additional actions
are performed in the case of a formal object of mode in (see 12.4).

**To be honest:** Actually, the actual is evaluated only if evaluation is defined for that kind of construct — we don't
actually “evaluate” subtype_marks.
NOTES
5 If a formal type is not tagged, then the type is treated as an untagged type within the generic body. Deriving from such a type in a generic body is permitted; the new type does not get a new tag value, even if the actual is tagged. Overriding operations for such a derived type cannot be dispatched to from outside the instance.

**Ramification:** If two overloaded subprograms declared in a generic package specification differ only by the (formal) type of their parameters and results, then there exist legal instantiations for which all calls of these subprograms from outside the instance are ambiguous. For example:

```ada
generic
  type A is (<>);
  type B is private;
package G is
  function Next(X : A) return A;
  function Next(X : B) return B;
end G;
package P is new G(A => Boolean, B => Boolean);
-- All calls of P.Next are ambiguous.
```

**Ramification:** The following example illustrates some of the subtleties of the substitution of formals and actuals:

```ada
generic
  type T1 is private;
  -- A predefined "=" operator is implicitly declared here:
  -- function "="(Left, Right : T1) return Boolean;
  -- Call this "=".
package G is
  subtype S1 is T1; -- So we can get our hands on the type from
  -- outside an instance.
  type T2 is new T1;
  -- An inherited "=" operator is implicitly declared here:
  -- function "="(Left, Right : T2) return Boolean;
  -- Call this "=".
  T1_Obj : T1 := ...;
  Bool_1 : Boolean := T1_Obj = T1_Obj;
  T2_Obj : T2 := ...;
  Bool_2 : Boolean := T2_Obj = T2_Obj;
end G;
...
package P is
  type My_Int is new Integer;
  -- A predefined "=" operator is implicitly declared here:
  -- function "="(Left, Right : My_Int) return Boolean;
  -- Call this "=".
  function "="(X, Y : My_Int) return Boolean;
  -- Call this "=".
  -- "=" is hidden from all visibility by "=".
  -- Nonetheless, "=" can "reemerge" in certain circumstances.
end P;
use P;
...
package I is new G(T1 => My_Int); -- "=" is declared in I (see below).
use I;
Another_T1_Obj : S1 := 13; -- Can't denote T1, but S1 will do.
Bool_3 : Boolean := Another_T1_Obj = Another_T1_Obj;
Another_T2_Obj : T2 := 45;
Bool_4 : Boolean := Another_T2_Obj = Another_T2_Obj;
Double : T2 := T2_Obj + Another_T2_Obj;
```

In the instance I, there is a copy of "=" (call it "="), and "=" (call it "="). The "=" and "=" declare views of the predefined "=" of My_Int (that is, "="). In the initialization of Bool_1 and Bool_2 in the generic unit G, the names "=" and "=" denote "=" and "=" respectively. Therefore, the copies of these names in the instances denote "=" and "=" respectively. Thus, the initialization of I.Bool_1 and I.Bool_2 call the predefined equality operator of My_Int; they will not call "=".

The declarations "=" and "=" are hidden from all visibility. This prevents them from being called from outside the instance.

The declaration of Bool_3 calls "=".

The instance I also contains implicit declarations of the primitive operators of T2, such as "=" (call it "=") and "-". These operations cannot be called from within the instance, but the declaration of Bool_4 calls "=".
Examples

Examples of generic instantiations (see 12.1):

```ada
procedure Swap is new Exchange(Elem => Integer);
procedure Swap is new Exchange(Character);  -- Swap is overloaded
function Square is new Squaring(Integer);  -- "*" of Integer used by default
function Square is new Squaring(Item => Matrix, "*" => Matrix_Product);
package Int_Vectors is new On_Vectors(Integer, Table, "+");
```

Examples of uses of instantiated units:

```ada
Swap(A, B);
A := Square(A);
T : Table(1 .. 5) := (10, 20, 30, 40, 50);
N : Integer := Int_Vectors.Sigma(T);  -- 150 (see 12.2, "Generic Bodies" for the body of Sigma)
use Int_Vectors;
M : Integer := Sigma(T);  -- 150
```

Inconsistencies With Ada 83

In Ada 83, all explicit actuals are evaluated before all defaults, and the defaults are evaluated in the order of the formal declarations. This ordering requirement is relaxed in Ada 95.

Incompatibilities With Ada 83

We have attempted to remove every violation of the contract model. Any remaining contract model violations should be considered bugs in the RM95. The unfortunate property of reverting to the predefined operators of the actual types is retained for upward compatibility. (Note that fixing this would require subtype conformance rules.) However, tagged types do not revert in this sense.

Extensions to Ada 83

The syntax rule for `explicit_generic_actual_parameter` is modified to allow a `package_instance_name`.

Wording Changes from Ada 83

The fact that named associations cannot be used for two formal subprograms with the same defining name is moved to AARM-only material, because it is a ramification of other rules, and because it is not of interest to the average user.

Extensions to Ada 95

```ada
\{AI95-00114-01\} The rule that "An explicit `explicit_generic_actual_parameter` shall not be supplied more than once for a given `generic_formal_parameter generic_formal_parameter" seems to be missing from RM83, although it was clearly the intent.
```

In the explanation that the instance is a copy of the template, we have left out RM83-12.3(5)'s “apart from the generic formal part”, because it seems that things in the formal part still need to exist in instances. This is particularly true for generic formal packages, where you're sometimes allowed to reach in and denote the formals of the formal package from outside it. This simplifies the explanation of what each name in an instance denotes: there are just two cases: the declaration can be inside or outside (where inside needs to include the generic unit itself). Note that the RM83 approach of listing many cases (see RM83-12.5(14)) would have become even more unwieldy with the addition of generic formal packages, and the declarations that occur therein.

We have corrected the definition of the elaboration of a `generic_instantiation` (RM83-12.3(17)); we don't elaborate entities, and the instance is not “implicit.”

In RM83, there is a rule saying the formal and actual shall match, and then there is much text defining what it means to match. Here, we simply state all the latter text as rules. For example, "A formal foo is matched by an actual greenish bar" becomes "For a formal foo, the actual shall be a greenish bar." This is necessary to split the Name Resolution Rules from the Legality Rules. Besides, there's really no need to define the concept of matching for generic parameters.

Extensions to Ada 2005

```ada
\{AI05-0183-1\} An optional `aspect_specification` can be used in a `generic_instantiation`. This is described in 13.1.1.
```
12.4 Formal Objects

[ A generic formal object can be used to pass a value or variable to a generic unit.]

Language Design Principles

A generic formal object of mode in is like a constant initialized to the value of the explicit_generic_actual_parameter.

A generic formal object of mode in out is like a renaming of the explicit_generic_actual_parameter.

Syntax

\[\text{formal_object_declaration ::= defining_identifier_list : mode \{null_exclusion\} subtype_mark \{= default_expression\} \{aspect_specification\};}\]

Name Resolution Rules

The expected type for the default_expression, if any, of a formal object is the type of the formal object. For a generic formal object of mode in, the expected type for the actual is the type of the formal. For a generic formal object of mode in out, the type of the actual shall resolve to the type determined by the subtype_mark, or for a formal_object_declaration with an access_definition, to a specific anonymous access type. If the anonymous access type is an access-to-object type, the type of the actual shall have the same designated type as that of the access_definition. If the anonymous access type is an access-to-subprogram type, the type of the actual shall have a designated profile which is type conformant with that of the access_definition of the formal.

Reason: See the corresponding rule for object_renaming_declarations for a discussion of the reason for this rule.

Legality Rules

If a generic formal object has a default_expression, then the mode shall be in [(either explicitly or by default)]; otherwise, its mode shall be either in or in out.

Ramification: Mode out is not allowed for generic formal objects.

For a generic formal object of mode in, the actual shall be an expression. For a generic formal object of mode in out, the actual shall be a name that denotes a variable for which renaming is allowed (see 8.5.1).

To be honest: The part of this that requires an expression or name is a Name Resolution Rule, but that's too pedantic to worry about. (The part about denoting a variable, and renaming being allowed, is most certainly not a Name Resolution Rule.)

In the case where the type of the formal is defined by an access_definition, the type of the actual and the type of the formal of mode in shall be nonlimited.

- shall both be access-to-object types with statically matching designated subtypes and with both or neither being access-to-constant types; or
- shall both be access-to-subprogram types with subtype conformant designated profiles.
For a formal_object_declaration with a null_exclusion or an access_definition that has a null_exclusion:

- if the actual matching the formal_object_declaration denotes the generic formal object of another generic unit G, and the instantiating containing the actual occurs within the body of G or within the body of a generic unit declared within the declarative region of G, then the declaration of the formal object of G shall have a null_exclusion;

- otherwise, the subtype of the actual matching the formal_object_declaration shall exclude null.

In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Reason: This rule prevents “lying”. Null must never be the value of an object with an explicit null_exclusion. The first bullet is an assume-the-worst rule which prevents trouble in generic bodies (including bodies of child units) when the subtype of the formal object excludes null implicitly. Since a generic formal object is like a constant of mode in initialized to the value of the actual, a limited type would not make sense, since initializing a constant is not allowed for a limited type. That is, generic formal objects of mode in are passed by copy, and limited types are not supposed to be copied.

Static Semantics

A formal_object_declaration declares a generic formal object. The default mode is in. For a formal object of mode in, the nominal subtype is the one denoted by the subtype_mark or access_definition in the declaration of the formal. For a formal object of mode in out, its type is determined by the subtype_mark or access_definition in the declaration; its nominal subtype is nonstatic, even if the subtype_mark denotes a static subtype; for a composite type, its nominal subtype is unconstrained if the first subtype of the type is unconstrained, even if the subtype_mark denotes a constrained subtype.

Reason: We require that the subtype is unconstrained because a formal in out acts like a renaming, and thus the given subtype is ignored for purposes of matching; any value of the type can be passed. Thus we can assume only that the object is constrained if the first subtype is constrained (and thus there can be no unconstrained subtypes for the type). If we didn't do this, it would be possible to rename or take ’Access of components that could disappear due to an assignment to the whole object.

Discussion: The two “even if” clauses are OK even though they don't mention access_definitions; an access subtype can neither be a static subtype nor be a composite type.

In an instance, a formal_object_declaration of mode in is a full constant declaration and declares a new stand-alone constant object whose initialization expression is the actual, whereas a formal_object_declaration of mode in out declares a view whose properties are identical to those of the actual.

Ramification: These rules imply that generic formal objects of mode in are passed by copy (or are built-in-place for a limited type), whereas generic formal objects of mode in out are passed by reference.

Initialization and finalization happen for the constant declared by a formal_object_declaration of mode in as for any constant; see 3.3.1, “Object Declarations” and 7.6, “Assignment and Finalization”.

In an instance, the subtype of a generic formal object of mode in is as for the equivalent constant. In an instance, the subtype of a generic formal object of mode in out is the subtype of the corresponding generic actual.

Dynamic Semantics

For the evaluation of a generic_association for a formal object of mode in, a constant object is created, the value of the actual parameter is converted to the nominal subtype of the formal object, and assigned to the object[ including any value adjustment — see 7.6].

Ramification: This includes evaluating the actual and doing a subtype conversion, which might raise an exception.

Discussion: The rule for evaluating a generic_association for a formal object of mode in out is covered by the general Dynamic Semantics rule in 12.3.
NOTES
6 The constraints that apply to a generic formal object of mode \texttt{in out} are those of the corresponding generic actual parameter (not those implied by the \texttt{subtype_mark} that appears in the \texttt{formal_object_declaration}). Therefore, to avoid confusion, it is recommended that the name of a first subtype be used for the declaration of such a formal object.

\textbf{Ramification:} Constraint checks are done at instantiation time for formal objects of mode \texttt{in}, but not for formal objects of mode \texttt{in out}.

\textit{Extensions to Ada 83}
In Ada 83, it is forbidden to pass a (nongeneric) formal parameter of mode \texttt{out}, or a subcomponent thereof, to a generic formal object of mode \texttt{in out}. This restriction is removed in Ada 95.

\textit{Wording Changes from Ada 83}
We make “mode” explicit in the syntax. RM83 refers to the mode without saying what it is. This is also more uniform with the way (nongeneric) formal parameters are defined.

We considered allowing mode \texttt{out} in Ada 95, for uniformity with (nongeneric) formal parameters. The semantics would be identical for modes \texttt{in out} and \texttt{out}. (Note that generic formal objects of mode \texttt{in out} are passed by reference. Note that for (nongeneric) formal parameters that are allowed to be passed by reference, the semantics of \texttt{in out} and \texttt{out} is the same. The difference might serve as documentation. The same would be true for generic formal objects, if \texttt{out} were allowed, so it would be consistent.) We decided not to make this change, because it does not produce any important benefit, and any change has some cost.

\textit{Extensions to Ada 95}
\begin{itemize}
\item \{AI95-00287-01\} A generic formal \texttt{in} object can have a limited type. The actual for such an object must be built-in-place via a \texttt{function_call} or \texttt{aggregate}, see 7.5.
\item \{AI95-00423-01\} A generic formal object can have a \texttt{null exclusion} or an anonymous access type.
\end{itemize}

\textit{Wording Changes from Ada 95}
\begin{itemize}
\item \{AI95-00255-01\} Clarified that the nominal subtype of a composite formal \texttt{in out} object is unconstrained if the first subtype of the type is unconstrained.
\item \{AI95-00269-01\} Clarified that a formal \texttt{in} object can be static when referenced from outside of the instance (by declaring such an object to be a full constant declaration).
\end{itemize}

\textit{Extensions to Ada 2005}
\begin{itemize}
\item \{AI05-0183-1\} An optional \texttt{aspect_specification} can be used in a \texttt{formal_object_declaration}. This is described in 13.1.1.
\end{itemize}

12.5 Formal Types

\begin{itemize}
\item \{AI95-00442-01\} [A generic formal subtype can be used to pass to a generic unit a subtype whose type is in a certain \texttt{category} of types.]
\end{itemize}

\textbf{Reason:} We considered having intermediate syntactic categories \texttt{formal Integer_type_definition}, \texttt{formal real_type_definition}, and \texttt{formal fixed_point_definition}, to be more uniform with the syntax rules for nongeneric-formal types. However, that would make the rules for formal types slightly more complicated, and it would cause confusion, since \texttt{formal discrete_type_definition} would not fit into the scheme very well.

\textit{Syntax}
\begin{itemize}
\item \{AI05-0213-1\} \texttt{formal_type_declaration ::=}
\begin{itemize}
\item \texttt{formal_complete_type_declaration}
\item \texttt{formal_incomplete_type_declaration type defining_identifier[discriminant_part] is formal_type_definition;}
\end{itemize}
\item \{AI05-0183-1\} \{AI05-0213-1\} \texttt{formal_complete_type_declaration ::=}
\begin{itemize}
\item \texttt{type defining_identifier[discriminant_part] is formal_type_definition [aspect_specification];}
\end{itemize}
\end{itemize}
formal_incomplete_type_declaration ::= 
  type defining_identifier[discriminant_part][is tagged];

formal_type_definition ::= 
  formal_private_type_definition 
  | formal_derived_type_definition 
  | formal_discrete_type_definition 
  | formal_signed_integer_type_definition 
  | formal_modular_type_definition 
  | formal_floating_point_definition 
  | formal_ordinary_fixed_point_definition 
  | formal_decimal_fixed_point_definition 
  | formal_array_type_definition 
  | formal_access_type_definition 
  | formal_interface_type_definition

Legality Rules

For a generic formal subtype, the actual shall be a subtype_mark; it denotes the (generic) actual subtype.

Ramification: When we say simply “formal” or “actual” (for a generic formal that denotes a subtype) we’re talking about the subtype, not the type, since a name that denotes a formal_type_declaration denotes a subtype, and the corresponding actual also denotes a subtype.

Static Semantics

A formal_type_declaration declares a (generic) formal type, and its first subtype, the (generic) formal subtype.

Ramification: A subtype (other than the first subtype) of a generic formal type is not a generic formal subtype.

Reason: This rule is clearer with the flat syntax rule for formal_type_definition given above. Adding formal_integer_type_definition and others would make this rule harder to state clearly.

We use “category’ rather than “class” above, because the requirement that classes are closed under derivation is not important here. Moreover, there are interesting categories that are not closed under derivation. For instance, limited and interface are categories that do not form classes.

Legality Rules

The actual type shall be in the categoryclass determined for the formal.

Ramification: For example, if the categoryclass determined for the formal is the categoryclass of all discrete types, then the actual has to be discrete.

Note that this rule does not require the actual to belong to every categoryclass to which the formal belongs. For example, formal private types are in the categoryclass of composite types, but the actual need not be composite. Furthermore, one can imagine an infinite number of categoryclasses that are just arbitrary sets of types that obey the closed under derivation rule, and are therefore technically classes (even though we don't give them names, since they are uninteresting). We don't want this rule to apply to those categoryclasses.

“Limited” is not an interesting categoryclass, but “nonlimited” is; it is legal to pass a nonlimited type to a limited formal type, but not the other way around. The reserved word limited really represents a categoryclass containing both limited and nonlimited types. “Private” is not a category for this purposeclass; a generic formal private type accepts both private and nonprivate actual types.
It is legal to pass a class-wide subtype as the actual if it is in the right category, so long as the formal has unknown discriminants.

Static Semantics

The formal type also belongs to each category that contains the determined category. The primitive subprograms of the type are as for any type in the determined category. For a formal type other than a formal derived type, these are the predefined operators of the type. For an elementary formal type, the predefined operators are implicitly declared immediately after the declaration of the formal type. For a composite formal type, the predefined operators are implicitly declared either immediately after the declaration of the formal type, or later immediately within the declaration of the type.

In an instance, the copy of such an implicit declaration declares a view of the predefined operator of the actual type, even if this operator has been overridden for the actual type and even if it is never declared for the actual type. [The rules specific to formal derived types are given in 12.5.1.]

Ramification: All properties of the type are as for any type in the category. Some examples:

The primitive operations available are as defined by the language for each category. The form of constraint applicable to a formal type in a subtype_indication depends on the category of the type as for a nonformal type. The formal type is tagged if and only if it is declared as a tagged private type, or as a type derived from a (visibly) tagged type. (Note that the actual type might be tagged even if the formal type is not.)

Reason: The somewhat cryptic phrase “even if it is never declared” is intended to deal with the following oddity:

```ada
package Q is
  type T is limited private;
  private
    type T is range 1 .. 10;
  end Q;
  generic
    type A is array (Positive range <>) of T;
  package Q.G is
    A1, A2 : A (1 .. 1);
    private
      B : Boolean := A1 = A2;
    end Q.G;
  end Q;
end
with Q.G;
package R is
  type C is array (Positive range <>) of Q.T;
  package I is new Q.G (C); -- Where is the predefined "=" for C?
end R;
```

An "=" is available for the formal type A in the private part of Q.G. However, no "=" operator is ever declared for type C, because its component type Q.T is limited. Still, in the instance I the name "=" declares a view of the "=" for C which exists-but-is-never-declared.

NOTES

7 Generic formal types, like all types, are not named. Instead, a name can denote a generic formal subtype. Within a generic unit, a generic formal type is considered as being distinct from all other (formal or nonformal) types.

Proof: This follows from the fact that each formal_type_declaration declares a type.

8 A discriminant_part is allowed only for certain kinds of types, and therefore only for certain kinds of generic formal types. See 3.7.

Ramification: The term “formal floating point type” refers to a type defined by a formal_floating_point_definition. It does not include a formal derived type whose ancestor is floating point. Similar terminology applies to the other kinds of formal_type_definition.

Examples of generic formal types:

```ada
type Item is private;
type Buffer(Length : Natural) is limited private;
```
13. type  Enum  is  (<>);  
   type  Int  is  range  <>;  
   type  Angle  is  delta  <>;  
   type  Mass  is  digits  <>;  

   type  Table  is  array  (Enum)  of  Item;

15. Example of a generic formal part declaring a formal integer type:

   generic
   type  Rank  is  range  <>;
   First  :  Rank  :=  Rank'First;
   Second :  Rank  :=  First  +  1;  --  the  operator  "+"  of  the  type  Rank

16. Extensions to Ada 2005

   An optional aspect_specification can be used in a formal_type_declaration. This is described in 13.1.1.

12.5.1 Formal Private and Derived Types

   In its most general form, the category determined for a formal private type is all types, but the category can be restricted to only nonlimited types or to only tagged types; can be either limited or nonlimited, and either tagged or untagged; no more specific class is known for such a type. Similarly, the category for a formal incomplete type is all types but the category can be restricted to only tagged types; unlike other formal types, the actual type does not need to be able to be frozen (see 13.14). The category determined for a formal derived type is the derivation class rooted at the ancestor type.

   The first two rules are given normatively below, and the third rule is given normatively in 12.5; they are repeated here to give a capsule summary of what this subclause is about.

   The actual of a formal incomplete type does not need to be able to be frozen, the actual can be an incomplete type or a partial view before its completion.
Syntax

```
formal_private_type_definition ::= (abstract | tagged | limited) private  
{AI95-00251-01} {AI95-00419-01} {AI95-00443-01} formal_derived_type_definition ::=  
  [abstract | limited | synchronized] new subtype_mark [and interface_list] with private
```

Legality Rules

If a generic formal type declaration has a known_discriminant_part, then it shall not include a default_expression for a discriminant.

Ramification: Consequently, a generic formal subtype with a known_discriminant_part is an indefinite subtype, so the declaration of a stand-alone variable has to provide a constraint on such a subtype, either explicitly, or by its initial value.

```
{AI95-00401-01} {AI95-00419-01} {AI95-00443-01} {AI05-0237-1} The ancestor subtype of a formal derived type is the subtype denoted by the subtype_mark of the formal_derived_type_definition. For a formal derived type declaration, the reserved words with private shall appear if and only if the ancestor type is a tagged type; in this case the formal derived type is a private extension of the ancestor type and the ancestor shall not be a class-wide type. [Similarly, an interface_list or the optional reserved word abstract or synchronized shall appear only if the ancestor type is a tagged type]. The reserved word limited or synchronized shall appear only if the ancestor type [and any progenitor types] are limited types. The reserved word synchronized shall appear (rather than limited) if the ancestor type or any of the progenitor types are synchronized interfaces. The ancestor type shall be a limited interface if the reserved word synchronized appears.
```

Reason: We use the term “ancestor” here instead of “parent” because the actual can be any descendant of the ancestor, not necessarily a direct descendant.

```
{AI95-00419-01} {AI05-0005-1} We require the ancestor type to be limited when limited appears so that we avoid oddities like limited integer types. Normally, limited means “match anything” for a generic formal, but it was felt that allowing limited elementary types to be declared was just too weird. Integer still matches a formal limited private type; it is only a problem when the type is known to be elementary. Note that the progenitors are required to be limited by rules in 3.9.4, thus that part of the rule is redundant.
```

```
{AI95-00443-01} We require that synchronized appear if the ancestor or any of the progenitors are synchronized, so that property is explicitly given in the program text — it is not automatically inherited from the ancestors. However, it can be given even if neither the ancestor nor the progenitors are synchronized.
```

```
{AI95-00251-01} {AI95-00401-01} {AI95-00443-01} {AI05-0087-1} The actual type for a formal derived type shall be a descendant of [the ancestor type and] every progenitor of the formal type. If the formal type is nonlimited, the actual subtype shall be nonlimited. If the reserved word synchronized appears in the declaration of the formal derived type, the actual type shall be a synchronized tagged type.
```

Proof: The actual type has to be a descendant of the ancestor type, in order that it be in the correct class. Thus, that part of the rule is redundant.

Discussion: {AI05-0005-1} For a nonformal private extension, we require the partial view to be synchronized if the full view is synchronized tagged. This does not apply to a formal private extension — it is OK if the formal is not synchronized. Any attempt to extend the formal type will be rechecked in the instance, where the rule disallowing extending a synchronized noninterface type will be enforced. This is consistent with the “no hidden interfaces” rule also applying only to nonformal private extensions, as well as the rule that a limited nonformal private extension implies a limited full type. Formal private extensions are exempted from all these rules to enable the construction of generics that can be used with the widest possible range of types. In particular, an indefinite tagged limited formal private type can match any “concrete” actual tagged type.

```
{AI05-0087-1} A type (including formal types) derived from a limited interface could be nonlimited; we do not want a limited type derived from such an interface to match a nonlimited formal derived type. Otherwise, we could assign limited objects. Thus, we have to explicitly ban this case.
```

```
{AI05-0213-1} If the formal private or derived subtype is definite, then the actual subtype shall also be definite.
```

Ramification: On the other hand, for an indefinite formal subtype, the actual can be either definite or indefinite.
A formal incomplete type declaration declares a formal incomplete type. The only view of a formal incomplete type is an incomplete view. [Thus, a formal incomplete type is subject to the same usage restrictions as any other incomplete type — see 3.10.1.]

For a generic formal derived type with no discriminant_part:

- If the ancestor subtype is constrained, the actual subtype shall be constrained, and shall be statically compatible with the ancestor;

  **Ramification:** In other words, any constraint on the ancestor subtype is considered part of the “contract.”

- If the ancestor subtype is an unconstrained access or composite subtype, the actual subtype shall be unconstrained.

  **Reason:** This rule ensures that if a composite constraint is allowed on the formal, one is also allowed on the actual. If the ancestor subtype is an unconstrained scalar subtype, the actual is allowed to be constrained, since a scalar constraint does not cause further constraints to be illegal.

- If the ancestor subtype is an unconstrained discriminated subtype, then the actual shall have the same number of discriminants, and each discriminant of the actual shall correspond to a discriminant of the ancestor, in the sense of 3.7.

  **Reason:** This ensures that if a discriminant constraint is given on the formal subtype, the corresponding constraint in the instance will make sense, without additional run-time checks. This is not necessary for arrays, since the bounds cannot be overridden in a type extension. An unknown_discriminant_part may be used to relax these matching requirements.

- {AI05-0213-1} If the ancestor subtype is an access subtype, the actual subtype shall exclude null if and only if the ancestor subtype excludes null.

  **Reason:** We require that the “excludes null” property match, because it would be difficult to write a correct generic for an access type without knowing this property. Many typical algorithms and techniques will not work for a subtype that excludes null (setting an unused component to null, default-initialized objects, and so on). We want this sort of requirement to be reflected in the contract of the generic.

- {AI05-0213-1} The declaration of a formal derived type shall not have a known_discriminant_part. For a generic formal private or incomplete type with a known_discriminant_part:

  - The actual type shall be a type with the same number of discriminants.
  
  - The actual subtype shall be unconstrained.
  
  - The subtype of each discriminant of the actual type shall statically match the subtype of the corresponding discriminant of the formal type.

  **Reason:** We considered defining the first and third rule to be called “subtype conformance” for discriminant_parts. We rejected that idea, because it would require implicit (inherited) discriminant_parts, which seemed like too much mechanism.

  [For a generic formal type with an unknown_discriminant_part, the actual may, but need not, have discriminants, and may be definite or indefinite.]

**Static Semantics**

- {AI95-00442-01} The category_class determined for a formal private type is as follows:

  - **limited private** the category_class of all types

  - **private** the category_class of all nonlimited types

  - **tagged limited private** the category_class of all tagged types

  - **tagged private** the category_class of all nonlimited tagged types

  [The presence of the reserved word abstract determines whether the actual type may be abstract.]
The category determined for a formal incomplete type is the category of all types, unless the formal type declaration includes the reserved word `tagged'; in this case, it is the category of all tagged types.

A formal private or derived type is a private or derived type, respectively. A formal derived tagged type is a private extension. [A formal private or derived type is abstract if the reserved word `abstract' appears in its declaration.]

For a formal derived type, the characteristics of the ancestor type is a composite type that is not an array type, the formal type inherits components from the ancestor type (including components, but excluding discriminants if there is a new `discriminant_part' is not specified), predefined operators, and inherited user-defined primitive subprograms are determined by its ancestor type and its progenitor types (if any), in the same way that those of a derived type are determined by those of its parent type and its progenitor types, defined by a `derived_type_definition' (see 3.4 and 7.3.1). In an instance, the copy of an implicit declaration of a primitive subprogram of a formal derived type declares a view of the corresponding primitive subprogram of the ancestor or progenitor of the formal derived type, even if this primitive has been overridden for the actual type and even if it is never declared for the actual type. When the ancestor or progenitor of the formal derived type is itself a formal type, the copy of the implicit declaration declares a view of the corresponding copied operation of the ancestor or progenitor. [In the case of a formal private extension, however, the tag of the formal type is that of the actual type, so if the tag in a call is statically determined to be that of the formal type, the body executed will be that corresponding to the actual type.]

Ramification: The above rule defining the properties of primitive subprograms in an instance applies even if the subprogram has been overridden or hidden for the actual type. This rule is necessary for untagged types, because their primitive subprograms might have been overridden by operations that are not `subtype_conformant' with the operations defined for the class. For tagged types, the rule still applies, but the primitive subprograms will dispatch to the appropriate implementation based on the type and tag of the operands. Even for tagged types, the formal parameter names and `default_expression' are determined by those of the primitive subprograms of the specified ancestor type (for progenitor type, for subprograms inherited from an interface type).

For a `prefix S' that denotes a formal indefinite subtype, the following attribute is defined:

\[\text{S'Definite \{AI05-0264-1\}}\]  S'Definite yields True if the actual subtype corresponding to S is definite; otherwise, it yields False. The value of this attribute is of the predefined type Boolean.

Discussion: Whether an actual subtype is definite or indefinite may have a major effect on the algorithm used in a generic. For example, in a generic I/O package, whether to use fixed-length or variable-length records could depend on whether the actual is definite or indefinite. This attribute is essentially a replacement for the Constrained attribute, which is now considered obsolete.

Dynamic Semantics

In the case where a formal type basis tagged with unknown discriminants, and the actual type is a class-wide type T:

• For the purposes of defining the primitive operations of the formal type, each of the primitive operations of the actual type is considered to be a subprogram (with an intrinsic calling convention — see 6.3.1) whose body consists of a dispatching call upon the corresponding operation of T, with its formal parameters as the actual parameters. If it is a function, the result of the dispatching call is returned.
If the corresponding operation of \( T \) has no controlling formal parameters, then the controlling tag value is determined by the context of the call, according to the rules for tag-indeterminate calls (see 3.9.2 and 5.2). In the case where the tag would be statically determined to be that of the formal type, the call raises Program_Error. If such a function is renamed, any call on the renaming raises Program_Error.

Discussion: As it states in 6.3.1, the convention of an inherited subprogram of a generic formal tagged type with unknown discriminants is intrinsic.

In the case of a corresponding primitive of \( T \) with no controlling formal parameters, the context of the call provides the controlling tag value for the dispatch. If no tag is provided by context, Program_Error is raised rather than resorting to a nondispatching call. For example:

```ada
generic
    type NT<> is new T with private;
    -- Assume \( T \) has operation "Function Empty return T;"
package G is
    procedure Test(X : in out NT);
end G;

package body G is
    procedure Test(X : in out NT)
    begin
        X := Empty;  -- Dispatching based on \( X'Tag \) takes place if actual is class-wide.
        declare
            Y : NT := Empty;
            -- Place is no tag provided by context.
        begin
            X := Y;  -- We never get this far.
        end:
    end Test;
end G;

type T1 is new T with null record;
package I is new G(T1'Class);
```

NOTES

9 {AI95-00442-01} In accordance with the general rule that the actual type shall belong to the category class determined for the formal (see 12.5, “Formal Types”):

- If the formal type is nonlimited, then so shall be the actual;
- For a formal derived type, the actual shall be in the class rooted at the ancestor subtype.

10 The actual type can be abstract only if the formal type is abstract (see 3.9.3).

Reason: This is necessary to avoid contract model problems, since one or more of its primitive subprograms are abstract; it is forbidden to create objects of the type, or to declare functions returning the type.

Ramification: On the other hand, it is OK to pass a nonabstract actual to an abstract formal — abstract on the formal indicates that the actual might be abstract.

11 If the formal has a discriminant_part, the actual can be either definite or indefinite. Otherwise, the actual has to be definite.

In compatibilities with Ada 83

Ada 83 does not have unknown_discriminant_parts, so it allows indefinite subtypes to be passed to definite formals, and applies a legality rule to the instance body. This is a contract model violation. Ada 95 disallows such cases at the point of the instantiation. The workaround is to add (<> as the discriminant_part of any formal subtype if it is intended to be used with indefinite actuals. If that's the intent, then there can't be anything in the generic body that would require a definite subtype.

The check for discriminant subtype matching is changed from a run-time check to a compile-time check.

Extensions to Ada 95

A generic formal derived type can include progenitors (interfaces) as well as a primary ancestor. It also may include limited to indicate that it is a limited type, and synchronized to indicate that it is a synchronized type.
12.5.2 Formal Scalar Types

A formal scalar type is one defined by any of the formal_type_definitions in this subclause. [The category_class determined for a formal scalar type is the category of all discrete, signed integer, modular, floating point, ordinary fixed point, or decimal types.]

Proof: {AI95-00442-01} The second rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about.

Ramification: {AI95-00442-01} The “category of a type” includes any classes that the type belongs to.

Syntax

formal_discrete_type_definition ::= (<>)
formal_signed_integer_type_definition ::= range <>
formal_modular_type_definition ::= mod <>
formal_floating_point_definition ::= digits <>
formal_ordinary_fixed_point_definition ::= delta <>
formal_decimal_fixed_point_definition ::= delta <> digits <>
The actual type for a formal scalar type shall not be a nonstandard numeric type.

**Reason:** This restriction is necessary because nonstandard numeric types have some number of restrictions on their use, which could cause contract model problems in a generic body. Note that nonstandard numeric types can be passed to formal derived and formal private subtypes, assuming they obey all the other rules, and assuming the implementation allows it (being nonstandard means the implementation might disallow anything).

NOTES
12 The actual type shall be in the class of types implied by the syntactic category of the formal type definition (see 12.5, “Formal Types”). For example, the actual for a formal_modular_type_definition shall be a modular type.

**Wording Changes from Ada 95**

\{AI95-00442-01\} We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class).

12.5.3 Formal Array Types

\{AI95-00442-01\} [The category_class determined for a formal array type is the category_class of all array types.]

**Proof:** \{AI95-00442-01\} This rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about.

**Syntax**

\[
\text{formal_array_type_definition ::= array_type_definition}
\]

**Legality Rules**

3 The only form of discrete_subtype_definition that is allowed within the declaration of a generic formal (constrained) array subtype is a subtype_mark.

**Reason:** The reason is the same as for forbidding constraints in subtype_indications (see 12.1).

3.a For a formal array subtype, the actual subtype shall satisfy the following conditions:

4 • The formal array type and the actual array type shall have the same dimensionality; the formal subtype and the actual subtype shall be either both constrained or both unconstrained.

5 • For each index position, the index types shall be the same, and the index subtypes (if unconstrained), or the index ranges (if constrained), shall statically match (see 4.9.1).

6 • The component subtypes of the formal and actual array types shall statically match.

7 • If the formal type has aliased components, then so shall the actual.

8.a **Ramification:** On the other hand, if the formal's components are not aliased, then the actual's components can be either aliased or not.

**Examples**

Example of formal array types:

```ada
-- given the generic package

generic
  type Item is private;
  type Index is (<>);
  type Vector is array (Index range <>) of Item;
  type Table is array (Index) of Item;
package P is
  ...
end P;
-- and the types
```

12.5.2 Formal Scalar Types
type Mix is array (Color range <>) of Boolean;
type Option is array (Color) of Boolean;

-- then Mix can match Vector and Option can match Table
package R is new P(Item => Boolean, Index => Color,
Vector => Mix, Table => Option);

-- Note that Mix cannot match Table and Option cannot match Vector

Incompatibilities With Ada 83

The check for matching of component subtypes and index subtypes or index ranges is changed from a run-time check to a compile-time check. The Ada 83 rule that "If the component type is not a scalar type, then the component subtypes shall be either both constrained or both unconstrained" is removed, since it is subsumed by static matching. Likewise, the rules requiring that component types be the same is subsumed.

Wording Changes from Ada 95

{AI95-00442-01} We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class).

12.5.4 Formal Access Types

{AI95-00442-01} [The category class determined for a formal access type is the category class of all access types.]

Proof: {AI95-00442-01} This rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about.

Syntax
formal_access_type_definition ::= access_type_definition

Legality Rules

For a formal access-to-object type, the designated subtypes of the formal and actual types shall statically match.

{AI95-00231-01} If and only if the general_access_modifier constant applies to the formal, the actual shall be an access-to-constant type. If the general_access_modifier all applies to the formal, then the actual shall be a general access-to-variable type (see 3.10). If and only if the formal subtype excludes null, the actual subtype shall exclude null.

Ramification: If no _modifier applies to the formal, then the actual type may be either a pool-specific or a general access-to-variable type.

Reason: {8652/0109} {AI95-00025-01} Matching an access-to-variable to a formal access-to-constant type cannot be allowed. If it were allowed, it would be possible to create an access-to-variable value designating a constant.

{AI95-00231-01} We require that the “excludes null” property match, because it would be difficult to write a correct generic for a formal access type without knowing this property. Many typical algorithms and techniques will not work for a subtype that excludes null (setting an unused component to null, default-initialized objects, and so on). Even Ada.Unchecked_Deallocation would fail for a subtype that excludes null. Most generics would end up with comments saying that they are not intended to work for subtypes that exclude null. We would rather that this sort of requirement be reflected in the contract of the generic.

{AI05-0239-1} {AI05-0288-1} For a formal access-to-subprogram subtype, the designated profiles of the formal and the actual shall be subtype conformant, mode conformant, and the calling convention of the actual shall be protected if and only if that of the formal is protected.

Reason: {AI05-0288-1} We considered requiring subtype conformance here, but mode conformance is more flexible, given that there is no way in general to specify the convention of the formal.
### 12.5.4 Formal Access Types

**Examples**

Example of formal access types:

```ada
generic
  type Node is private;
  type Link is access Node;
package P is
  ...
end P;
```

-- can be matched by the actual types

```ada
type Car;
type Car_Name is access Car;
type Car is
  record
    Pred, Succ : Car_Name;
    Number     : License_Number;
    Owner      : Person;
  end record;
```

-- in the following generic instantiation

```ada
package R is new P(Node => Car, Link => Car_Name);
```

**Incompatibilities With Ada 83**

The check for matching of designated subtypes is changed from a run-time check to a compile-time check. The Ada 83 rule that “If the designated type is other than a scalar type, then the designated subtypes shall be either both constrained or both unconstrained” is removed, since it is subsumed by static matching.

**Extensions to Ada 83**

Formal access-to-subprogram subtypes and formal general access types are new concepts.

**Wording Changes from Ada 95**

[A195-00231-01] Added a matching rule for subtypes that exclude null.

[A195-00442-01] We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class).

**Incompatibilities With Ada 2005**

[A105-0288-1] Correction: Matching of formal access-to-subprogram types now uses subtype conformance rather than mode conformance, which is needed to plug a hole. This could cause some instantiations legal in Ada 95 and Ada 2005 to be rejected in Ada 2012. We believe that formal access-to-subprogram types occur rarely, and actuals that are not subtype conformant are rarer still, so this should not happen often. (In addition, one popular compiler has a bug that causes such instances to be rejected, so no code compiled with that compiler could have an incompatibility.)

### 12.5.5 Formal Interface Types

[A195-00251-01] The category determined for a formal interface type is the category of all interface types.

**Proof:** [A195-00442-01] This rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about.

**Ramification:** Here we’re taking advantage of our switch in terminology from “determined class” to “determined category”; by saying “category” rather than “class”, we require that any actual type be an interface type, not just some type derived from an interface type.

**Syntax**

[A195-00251-01] `formal_interface_type_definition ::= interface_type_definition`
Legality Rules

{AI95-00251} {AI95-00401} The actual type shall be a descendant of every progenitor of the formal type.

{AI95-00345} The actual type shall be a limited, task, protected, or synchronized interface if and only if the formal type is also, respectively, a limited, task, protected, or synchronized interface.

Discussion: We require the kind of interface type to match exactly because without that it is almost impossible to properly implement the interface.

Examples

{AI95-00433-01} type Root_Work_Item is tagged private;

{AI95-00433-01} generic
    type Managed_Task is task interface;
    type Work_Item<> is new Root_Work_Item with private;
package Server_Manager is
    task type Server is new Managed_Task with
        entry Start(Data : in out Work_Item);
end Server;
end Server_Manager;

{AI95-00433-01} This generic allows an application to establish a standard interface that all tasks need to implement so they can be managed appropriately by an application-specific scheduler.

Extensions to Ada 95

{AI95-00251-01} {AI95-00345-01} {AI95-00401-01} The formal interface type is new.

12.6 Formal Subprograms

[ Formal subprograms can be used to pass callable entities to a generic unit.]

Language Design Principles

Generic formal subprograms are like renames of the explicit generic_actual_parameter.

Syntax

{AI95-00260-02} formal_subprogram_declaration ::= formal_concrete_subprogram_declaration
    | formal_abstract_subprogram_declaration with subprogram_specification [is subprogram_default];

{AI95-00260-02} {AI05-0183-1} formal_concrete_subprogram_declaration ::=__ [aspect_specification];

{AI95-00260-02} {AI05-0183-1} formal_abstract_subprogram_declaration ::=__ [aspect_specification];

{AI95-00348-01} subprogram_default ::= default_name | <> | null

default_name ::= name

{AI95-00260-02} {AI95-00348-01} A subprogram_default of null shall not be specified for a formal function or for a formal abstract_subprogram_declaration.

Reason: There are no null functions because the return value has to be constructed somehow. We don't allow null for abstract formal procedures, as the operation is dispatching. It doesn't seem appropriate (or useful) to say that the implementation of something is null in the formal type and all possible descendants of that type. This also would define a dispatching operation that doesn't correspond to a slot in the tag of the controlling type, which would be a new concept. Finally, additional rules would be needed to define the meaning of a dispatching null procedure (for instance,
the convention of such a subprogram should be intrinsic, but that's not what the language says). It doesn't seem worth the effort.

Name Resolution Rules

The expected profile for the default_name, if any, is that of the formal subprogram.

Ramification: \{AI05-0299-1\} This rule, unlike others in this subclause, is observed at compile time of the generic_declaration.

The evaluation of the default_name takes place during the elaboration of each instantiation that uses the default, as defined in 12.3, “Generic Instantiation”.

For a generic formal subprogram, the expected profile for the actual is that of the formal subprogram.

Legality Rules

\{AI05-0239-1\} The profiles of the formal and any named default shall be mode_conformant.

Ramification: \{AI05-0299-1\} This rule, unlike others in this subclause, is checked at compile time of the generic_declaration.

\{AI05-0239-1\} The profiles of the formal and actual shall be mode_conformant.

\{AI95-00423-01\} For a parameter or result subtype of a formal_subprogram_declaration that has an explicit null_exclusion:

- if the actual matching the formal_subprogram_declaration denotes a generic formal object of another generic unit \(G\), and the instantiation containing the actual that occurs within the body of a generic unit \(G\) or within the body of a generic unit declared within the declarative region of the generic unit \(G\), then the corresponding parameter or result type of the formal subprogram of \(G\) shall have a null_exclusion;

- otherwise, the subtype of the corresponding parameter or result type of the actual matching the formal_subprogram_declaration shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

Reason: This rule prevents “lying”. Null must never be the value of a parameter or result with an explicit null_exclusion. The first bullet is an assume-the-worst rule which prevents trouble in generic bodies (including bodies of child generics) when the formal subtype excludes null implicitly.

\{AI95-00260-02\} If a formal parameter of a formal_abstract_subprogram_declaration is of a specific tagged type \(T\) or of an anonymous access type designating a specific tagged type \(T\), \(T\) is called a controlling type of the formal_abstract_subprogram_declaration. Similarly, if the result of a formal_abstract_subprogram_declaration for a function is of a specific tagged type \(T\) or of an anonymous access type designating a specific tagged type \(T\), \(T\) is called a controlling type of the formal_abstract_subprogram_declaration. A formal_abstract_subprogram_declaration shall have exactly one controlling type, and that type shall not be incomplete.

Ramification: The specific tagged type could be any of a formal tagged private type, a formal derived type, a formal interface type, or a normal tagged type. While the last case doesn't seem to be very useful, there isn't any good reason for disallowing it. This rule ensures that the operation is a dispatching operation of some type, and that we unambiguously know what that type is.

We informally call a subprogram declared by a formal_abstract_subprogram_declaration an abstract formal subprogram, but we do not use this term in normative wording. (We do use it often in these notes.)

\{AI95-00260-02\} The actual subprogram for a formal_abstract_subprogram_declaration shall be a dispatching operation of the controlling type or of the actual type corresponding to the controlling type.

To be honest: We mean the controlling type of the formal_abstract_subprogram_declaration, of course. Saying that gets unwieldy and redundant (so says at least one reviewer, anyway).
**Ramification:** This means that the actual is either a primitive operation of the controlling type, or an abstract formal subprogram. Also note that this prevents the controlling type from being class-wide (with one exception explained below), as only specific types have primitive operations (and a formal subprogram eventually has to have an actual that is a primitive of some type). This could happen in a case like:

```ada
generic
  type T<> is tagged private;
  with procedure Foo (Obj : in T) is abstract;
package P ...
package New_P is new P (Something'Class, Some_Proc);
```

The instantiation here is always illegal, because Some_Proc could never be a primitive operation of Something'Class (there are no such operations). That's good, because we want calls to Foo always to be dispatching calls.

Since it is possible for a formal tagged type to be instantiated with a class-wide type, it is possible for the (real) controlling type to be class-wide in one unusual case:

```ada
generic
  type NT<> is new T with private;
  -- Presume that T has the following primitive operation:
  -- with procedure Bar (Obj : in T);
package Gr ...
package body Gr is
  package New_P2 is new P (NT, Foo => Bar);
end Gr;
package New_Gr is new Gr (Something'Class);
```

The instantiation of New_P2 is legal, since Bar is a dispatching operation of the actual type of the controlling type of the abstract formal subprogram Foo. This is not a problem, since the rules given in 12.5.1 explain how this routine dispatches even though its parameter is class-wide.

Note that this legality rule never needs to be rechecked in an instance (that contains a nested instantiation). The rule only talks about the actual type of the instantiation; it does not require looking further; if the actual type is in fact a formal type, we do not intend looking at the actual for that formal.

**Static Semantics**

A **formal_subprogram_declaration** declares a generic formal subprogram. The types of the formal parameters and result, if any, of the formal subprogram are those determined by the **subtype_marks** given in the **formal_subprogram_declaration**; however, independent of the particular subtypes that are denoted by the **subtype_marks**, the nominal subtypes of the formal parameters and result, if any, are defined to be nonstatic, and unconstrained if of an array type ([no applicable index constraint is provided in a call on a formal subprogram]). In an instance, a **formal_subprogram_declaration** declares a view of the actual. The profile of this view takes its subtypes and calling convention from the original profile of the actual entity, while taking the formal parameter **names** and **default_expressions** from the profile given in the **formal_subprogram_declaration**. The view is a function or procedure, never an entry.

**Discussion:** This rule is intended to be the same as the one for renamings-as-declarations, where the **formal_subprogram_declaration** is analogous to a renaming-as-declaration, and the actual is analogous to the renamed view.

**AI05-0071-1** **AI05-0131-1** If a **subtype_mark** in the profile of the **formal_subprogram_declaration** denotes a formal private or formal derived type and the actual type for this formal type is a class-wide type **T**'Class, then for the purposes of resolving the corresponding actual subprogram at the point of the instantiation, certain implicit declarations may be available as possible resolutions as follows:

For each primitive subprogram of **T** that is directly visible at the point of the instantiation, and that has at least one controlling formal parameter, a corresponding implicitly declared subprogram with the same defining name, and having the same profile as the primitive subprogram except that **T** is systematically replaced by **T**'Class in the types of its profile, is potentially use-visible. The body of such a subprogram is as defined in 12.5.1 for primitive subprograms of a formal type when the actual type is class-wide.
Reason: \{AI05-0071-1\} \{AI05-0131-1\} This gives the same capabilities to formal subprograms as those that primitive operations of the formal type have when the actual type is class-wide. We do not want to discourage the use of explicit declarations for (formal) subprograms.

Implementation Note: \{AI05-0071-1\} \{AI05-0131-1\} Although the above wording seems to require constructing implicit versions of all of the primitive subprograms of type \( T \), it should be clear that a compiler only needs to consider those that could possibly resolve to the corresponding actual subprogram. For instance, if the formal subprogram is a procedure with two parameters, and the actual subprogram name is Bar (either given explicitly or by default), the compiler need not consider primitives that are functions, that have the wrong number of parameters, that have defining names other than Bar, and so on; thus it does not need to construct implicit declarations for those primitives.

Ramification: \{AI05-0071-1\} \{AI05-0131-1\} Functions that only have a controlling result and do not have a controlling parameter of \( T \) are not covered by this rule, as any call would be required to raise Program_Error by 12.5.1. It is better to detect the error earlier than at run time.

If a generic unit has a subprogram_default specified by a box, and the corresponding actual parameter is omitted, then it is equivalent to an explicit actual parameter that is a usage name identical to the defining name of the formal.

\{AI95-00348-01\} If a generic unit has a subprogram_default specified by the reserved word null, and the corresponding actual parameter is omitted, then it is equivalent to an explicit actual parameter that is a null procedure having the profile given in the formal subprogram_declaration.

\{AI95-00260-02\} The subprogram declared by a formal abstract subprogram_declaration with a controlling type \( T \) is a dispatching operation of type \( T \).

Reason: This is necessary to trigger all of the dispatching operation rules. It otherwise would not be considered a dispatching operation, as formal subprograms are never primitive operations.

NOTES
13 The matching rules for formal subprograms state requirements that are similar to those applying to subprogram_renaming Declarations (see 8.5.4). In particular, the name of a parameter of the formal subprogram need not be the same as that of the corresponding parameter of the actual subprogram; similarly, for these parameters, default expressions need not correspond.

14 The constraints that apply to a parameter of a formal subprogram are those of the corresponding formal parameter of the matching actual subprogram (not those implied by the corresponding subtype_mark in the _specification of the formal subprogram). A similar remark applies to the result of a function. Therefore, to avoid confusion, it is recommended that the name of a first subtype be used in any declaration of a formal subprogram.

15 The subtype specified for a formal parameter of a generic formal subprogram can be any visible subtype, including a generic formal subtype of the same generic_formal_part.

16 A formal subprogram is matched by an attribute of a type if the attribute is a function with a matching specification. An enumeration literal of a given type matches a parameterless formal function whose result type is the given type.

17 A default_name denotes an entity that is visible or directly visible at the place of the generic_declaration; a box used as a default is equivalent to a name that denotes an entity that is directly visible at the place of the _instantiation.

Proof: Visibility and name resolution are applied to the equivalent explicit actual parameter.

18 \{AI95-00260-02\} The actual subprogram cannot be abstract unless the formal subprogram is a formal abstract_subprogram_declaration (see 3.9.3).

19 \{AI95-00260-02\} The subprogram declared by a formal abstract subprogram_declaration is an abstract subprogram. All calls on a subprogram declared by a formal abstract subprogram_declaration must be dispatching calls. See 3.9.3.

20 \{AI95-00348-01\} A null procedure as a subprogram default has convention Intrinsic (see 6.3.1).

Proof: This is an implicitly declared subprogram, so it has convention Intrinsic as defined in 6.3.1.
Examples

Examples of generic formal subprograms:

```ada
with function "+"(X, Y : Item) return Item is <>;  
with function Image(X : Enum) return String is Enum'Image;  
with procedure Pre_Action(X : in Item) is null;  -- defaults to no action  
with procedure Write(S : not null access Root_Stream_Type'Class;  
  Desc : Descriptor),  
  is abstract Descriptor'Write;  -- see 13.13.2  
-- Dispatching operation on Descriptor with default  
-- given the generic procedure declaration  
generic  
  with procedure Action (X : in Item);  
procedure Iterate(Seq : in Item_Sequence);  
-- and the procedure  
procedure Put_Item(X : in Item);  
-- the following instantiation is possible  
procedure Put_List is new Iterate(Action => Put_Item);  
```

Extensions to Ada 95

```ada
{AI95-00260-02} The formal abstract subprogram declaration is new. It allows the passing of dispatching operations to generic units.

{AI95-00348-01} The formal subprogram default of null is new. It allows the default of a generic procedure to do nothing, such as for passing a debugging routine.
```

Wording Changes from Ada 95

```ada
{AI95-00423-01} Added matching rules for null exclusions.
```

Incompatibilities With Ada 2005

```ada
{AI05-0296-1} It is now illegal to declare a formal abstract subprogram whose controlling type is incomplete. It was never intended to allow that, and such a type would have to come from outside of the generic unit in Ada 2005, so it is unlikely to be useful. Moreover, a dispatching call on the subprogram is likely to fail in many implementations. So it is very unlikely that any code will need to be changed because of this new rule.
```

Extensions to Ada 2005

```ada
{AI05-0071-1} {AI05-0131-1} Correction: Added construction of implicit subprograms for primitives of class-wide actual types, to make it possible to import subprograms via formal subprograms as well as by implicit primitive operations of a formal type. (This is a Correction as it is very important for the usability of indefinite containers when instantiated with class-wide types; thus we want Ada 2005 implementations to support it.)

{AI05-0183-1} An optional aspect specification can be used in a formal concrete subprogram declaration and a formal abstract subprogram declaration. This is described in 13.1.1.
```

12.7 Formal Packages

[ Formal packages can be used to pass packages to a generic unit. The formal_package_declaration declares that the formal package is an instance of a given generic package. Upon instantiation, the actual package has to be an instance of that generic package.]

Syntax

```ada
{AI05-0183-1} formal_package_declaration ::=  
  with package defining_identifier is new generic_package_name formal_package_actual_part  
    __ aspect_specification;
```

12.7 Formal Packages

The **generic_package_name** shall denote a generic package (the *template* for the formal package); the formal package is an instance of the template.

**Legality Rules**

- **AI95-00317-01** formal_package_actual_part ::= 
  
  - [generic_actual_part]
  
  │ [formal_package_association {, formal_package_association} {, others => <>}] {<>} [generic_actual_part]

- **AI95-00317-01** formal_package_association ::= 
  
  - generic_association

- **AI95-00317-01** Any positional formal_package_associations shall precede any named formal_package_associations.

- **AI95-00317-01** The **generic_formal_parameter_selector_name** of a formal_package_association shall denote a **generic_formal_parameter_declaration** of the template. If two or more formal subprograms of the template have the same defining name, then named associations are not allowed for the corresponding actuals.

- **AI95-00398-01** A formal_package_actual_part shall contain at most one formal_package_association for each formal parameter. If the formal_package_actual_part does not include “others => <>”, each formal parameter without an association shall have a default_expression or subprogram_default.

- **AI05-0200-1** The rules for matching between formal_package_associations and the generic formals of the template are as follows:

  - **AI95-00317-01** If all of the formal_package_associations are given by generic associations, the explicit generic_actual_parameters of the formal_package_associations shall be legal for an instantiation of the template.

  - **AI95-00317-01** If a formal_package_association for a formal type T of the template is given by <>, then the formal_package_association for any other generic_formal_parameter_declaration of the template that mentions T directly or indirectly must be given by <> as well.

  **Discussion:** **AI05-0200-1** The above rule is simple to state, though it does not reflect the fact that the formal_package_functions like an instantiation of a special kind, where each box association for a generic_formal_parameter_declaration F is replaced with a new entity F' that has the same characteristics as F: if F is a formal discrete type then F' is a discrete type, if F is a formal subprogram then F' is a subprogram with a similar signature, etc. In practice this is achieved by making the association into a copy of the declaration of the generic formal.

- **AI95-00317-01** The actual shall be an instance of the template. If the formal_package_actual_part is (<> or (others => <>), [then the actual may be any instance of the template]; otherwise, certain of the actual parameters of the actual instance shall match the corresponding actual parameters of the formal_package_determined, (whether the actual parameter is given explicitly or by default), as follows:

  - **AI95-00317-01** If the formal_package_actual_part includes generic associations as well as associations with <>, then only the actual parameters specified explicitly with generic associations are required to match;

  - **AI95-00317-01** Otherwise, all actual parameters shall match, whether any actual parameter is given explicitly or by default.
The rules for matching of actual parameters between the actual instance and the formal package are as follows:

- For a formal object of mode in, the actuals match if they are static expressions with the same value, or if they statically denote the same constant, or if they are both the literal null.

  Reason: We can't simply require full conformance between the two actual parameter expressions, because the two expressions are being evaluated at different times.

- For a formal subtype, the actuals match if they denote statically matching subtypes.

- For other kinds of formals, the actuals match if they statically denote the same entity.

For the purposes of matching, any actual parameter that is the name of a formal object of mode in is replaced by the formal object's actual expression (recursively).

Static Semantics

A formal_package_declaration declares a generic formal package.

The visible part of a formal package includes the first list of basic_declarative_items of the package_specification. In addition, for each actual parameter that is not required to match, a copy of the declaration of the corresponding formal parameter of the template is included in the visible part of the formal package. If the copied declaration is for a formal type, copies of the implicit declarations of the primitive subprograms of the formal type are also included in the visible part of the formal_package_actual_part. It also includes the generic_formal_part of the template for the formal package.

Ramification: If the formal_package_actual_part is (<>), then the declarations that occur immediately within the generic_formal_part of the template for the formal package are visible outside the formal package, and can be denoted by expanded names outside the formal package. If only some of the actual parameters are given by <>, then the declaration corresponding to those parameters (but not the others) are made visible.

Reason: We always want either the actuals or the formals of an instance to be nameable, but never both. If both were nameable, one would get some funny anomalies since they denote the same entity, but, in the case of types at least, they might have different and inconsistent sets of primitive operators due to predefined operator "reemergence." Formal derived types exacerbate the difference. We want the implicit declarations of the generic_formal_part as well as the explicit declarations, so we get operations on the formal types.

Ramification: A generic formal package is a package, and is an instance. Hence, it is possible to pass a generic formal package as an actual to another generic formal package.

For the purposes of matching, if the actual instance A itself is a formal package, then the actual parameters of A are those specified explicitly or implicitly in the formal_package_actual_part for A, plus, for those not specified, the copies of the formal parameters of the template included in the visible part of A.

Example of a generic package with formal package parameters:

```ada
with Ada.Containers.Ordered_Maps; -- see A.18.6
generic
  with package Mapping_1 is new Ada.Containers.Ordered_Maps(<>);
  with package Mapping_2 is new Ada.Containers.Ordered_Maps
    (Key_Type => Mapping_1.Element_Type,
     others => <>);
package Ordered_Join is
  -- Provide a "join" between two mappings
  subtype Key_Type is Mapping_1.Key_Type;
  subtype Element_Type is Mapping_2.Element_Type;
  function Lookup(Key : Key_Type) return Element_Type;

  end Ordered_Join;
```

Examples
Example of an instantiation of a package with formal packages:

```ada
with Ada.Containers.Ordered_Maps;
package Symbol_Package is
    type String_Id is ...  
    type Symbol_Info is ...
    package String_Table is new AdaContainers.Ordered_Maps
        (Key_Type => String,
         Element_Type => String_Id);
    package Symbol_Table is new AdaContainers.Ordered_Maps
        (Key_Type => String_Id,
         Element_Type => Symbol_Info);
    package String_Info is new Ordered_Join(Mapping_1 => String_Table,
                                              Mapping_2 => Symbol_Table);
    Apple_Info : constant Symbol_Info := String_Info.Lookup("Apple");
end Symbol_Package;
```

Extensions to Ada 93

Formal packages are new to Ada 95.

Extensions to Ada 95

It's now allowed to mix actuals of a formal package that are specified with those that are not specified.

Wording Changes from Ada 95

Corrected the description of formal package matching to say that formal parameters are always replaced by their actual parameters (recursively). This matches the actual practice of compilers, as the ACATS has always required this behavior.

The description of which operations are visible in a formal package has been clarified. We also specify how matching is done when the actual is a formal package.

Incompatibilities With Ada 2005

Correction: Added missing rules for parameters of generic formal package that parallel those in 12.3, as well as some specific to <> parameters. These are technically incompatibilities because generic formal package parameters that Ada 95 and Ada 2005 would have considered legal now have to be rejected. But this should not be an issue in practice as such formal parameters could not have matched any actual generics. And it is quite likely that implementations already enforce some of these rules.

12.8 Example of a Generic Package

The following example provides a possible formulation of stacks by means of a generic package. The size of each stack and the type of the stack elements are provided as generic formal parameters.

Examples

This paragraph was deleted.
generic
  Size : Positive;
  type Item is private;
package Stack is
  procedure Push(E : in Item);
  procedure Pop (E : out Item);
  Overflow, Underflow : exception;
end Stack;

package body Stack is
  type Table is array (Positive range <>) of Item;
  Space : Table(1 .. Size);
  Index : Natural := 0;
begin
  if Index >= Size then
    raise Overflow;
  end if;
  Index := Index + 1;
  Space(Index) := E;
end Push;

begin
  if Index = 0 then
    raise Underflow;
  end if;
  E := Space(Index);
  Index := Index - 1;
end Pop;
end Stack;

Instances of this generic package can be obtained as follows:

package Stack_Int is new Stack(Size => 200, Item => Integer);
package Stack_Bool is new Stack(100, Boolean);

Thereafter, the procedures of the instantiated packages can be called as follows:

Stack_Int.Push(N);
Stack_Bool.Push(True);

Alternatively, a generic formulation of the type Stack can be given as follows (package body omitted):

generic
  type Item is private;
package On_Stacks is
  type Stack(Size : Positive) is limited private;
  procedure Push(S : in out Stack; E : in Item);
  procedure Pop (S : in out Stack; E : out Item);
  Overflow, Underflow : exception;
private
  type Table is array (Positive range <>) of Item;
  type Stack(Size : Positive) is
    record
      Space : Table(1 .. Size);
      Index : Natural := 0;
    end record;
end On_Stacks;
In order to use such a package, an instance has to be created and thereafter stacks of the corresponding
type can be declared:

```ada
declare
  package Stack_Real is new On_Stacks(Real); use Stack_Real;
  S : Stack(100);
begin
  ...
  Push(S, 2.54);
  ...
end;
```
13 Representation Issues

{8652/0009} {AI95-00137-01} {AI05-0299-1} [This clause describes features for querying and controlling certain aspects of entities and for interfacing to hardware.]

Wording Changes from Ada 83

{AI05-0299-1} The subclauses of this clause have been reorganized. This was necessary to preserve a logical order, given the new Ada 95 semantics given in this section.

13.1 Operational and Representation Aspects

{8652/0009} {AI95-00137-01} {AI05-0295-1} Representation and operational items can be used to specify aspects of entities. Two kinds of aspects of entities can be specified: aspects of representation and operational aspects. Representation aspects affect how the types and other entities of the language are to be mapped onto the underlying machine. Operational aspects specify other properties of entities.

{AI05-0183-1} {AI05-0295-1} Either kind of aspect of an entity may be specified by means of an aspect specification (see 13.1.1), which is an optional element of most kinds of declarations and applies to the entity or entities being declared. Aspects may also be specified by certain other constructs occurring subsequent to the declaration of the affected entity: a representation aspect value may be specified by means of a representation item and an operational aspect value may be specified by means of an operational item.

{8652/0009} {AI95-00137-01} There are three kinds of representation items: attribute_definition_clauses for representation attributes, enumeration_representation_clauses, record_representation_clauses, at_clauses, component_clauses, and representation_pragmas. Representation items specify how the types and other entities of the language are to be mapped onto the underlying machine. They can be provided to give more efficient representation or to interface with features that are outside the domain of the language (for example, peripheral hardware). Representation items also specify other specifiable properties of entities. A representation item applies to an entity identified by a local_name, which denotes an entity declared local to the current declarative region, or a library unit declared immediately preceding a representation pragma in a compilation.

{8652/0009} {AI95-00137-01} An operational item is an attribute_definition_clause for an operational attribute.

{8652/0009} {AI95-00137-01} [An operational item or a representation item applies to an entity identified by a local_name, which denotes an entity declared local to the current declarative region, or a library unit declared immediately preceding a representation pragma in a compilation.]

Language Design Principles

{8652/0009} {AI95-00137-01} {AI05-0295-1} Representation aspects. Aspects of representation are intended to refer to properties that need to be known before the compiler can generate code to create or access an entity. For instance, the size of an object needs to be known before the object can be created. Conversely, operational aspects are those that only need to be known before they can be used. For instance, how an object is read from a stream only needs to be known when a stream read is executed. Thus, aspects of representation aspects have stricter rules as to when they can be specified.

{AI95-00291-02} {AI05-0295-1} Confirming the value of an aspect with an operational or representation item should never change the semantics of the aspect. Thus Size = 8 (for example) means the same thing whether it was specified with a representation item or whether the compiler chose this value by default.

Glossary entry: An aspect is a specifiable property of an entity. An aspect may be specified by an aspect_specification on the declaration of the entity. Some aspects may be queried via attributes.
Syntax

```
{8652/0009} {AI95-00137-01} aspect_clauserepresentation_clause ::= attribute_definition_clause
| enumeration_representation_clause
| record_representation_clause
| at_clause

local_name ::= direct_name
| direct_name'attribute_designator
| library_unit_name
```

A representation pragma is allowed only at places where an aspect_clause_representation_clause or compilation_unit is allowed.

Name Resolution Rules

```
{8652/0009} {AI95-00137-01} In an operational item or a representation item, if the local_name is a direct_name, then it shall resolve to denote a declaration (or, in the case of a pragma, one or more declarations) that occurs immediately within the same declarative region as the representation-item. If the local_name has an attribute_designator, then it shall resolve to denote an implementation-defined component (see 13.5.1) or a class-wide type implicitly declared immediately within the same declarative region as the representation-item. A local_name that is a library_unit_name (only permitted in a representation pragma) shall resolve to denote the library_item that immediately precedes (except for other pragmas) the representation pragma.
```

Reason:

```
{8652/0009} {AI95-00137-01} This is a Name Resolution Rule, because we don't want an operational or representation item for X to be ambiguous just because there's another X declared in an outer declarative region. It doesn't make much difference, since most operational or representation items are for types or subtypes, and type and subtype names can't be overloaded.
```

Ramification:

```
{8652/0009} {AI95-00137-01} The visibility rules imply that the declaration has to occur before the operational or representation item.
```

Ramification:

```
{8652/0009} {AI95-00137-01} For objects, this implies that operational or representation items can be applied only to stand-alone objects.
```

Legality Rules

```
{8652/0009} {AI95-00137-01} The local_name of an aspect_clause_representation_clause or representation pragma shall statically denote an entity (or, in the case of a pragma, one or more entities) declared immediately preceding it in a compilation, or within the same declarative_part, package_specification, task_definition, protected_definition, or record_definition as the representation or operational item. If a local_name denotes a [local] callable entity, it may do so through a [local] subprogram_renaming_declaration [(as a way to resolve ambiguity in the presence of overloading)]; otherwise, the local_name shall not denote a renaming_declaration.
```

Discussion:

```
{AI95-00291-02} The representation of an object consists of a certain number of bits (the size of the object). For an object of an elementary type, these are the bits that are normally read or updated by
```
the machine code when loading, storing, or operating-on the value of the object. **For an object of a composite type, these are the bits reserved for this object, and include bits occupied by subcomponents of the object. If** this includes some padding bits, when the size of the object is greater than that of its subtype, the additional bits are padding bits.—**For an elementary object, these** such padding bits are considered to be part of the representation of the object, rather than being gaps between objects, if these bits are normally read and updated along with the others. For a composite object, padding bits might not be read or updated in any given composite operation, depending on the implementation.

**To be honest:** {AI95-00291-02} Discontiguous representations are allowed, but the ones we're interested in here are generally contiguous sequences of bits. **For a discontiguous representation, the size doesn't necessarily describe the “footprint” of the object in memory (that is, the amount of space taken in the address space for the object).**

**Discussion:** {AI95-00291-02} In the case of composite objects, we want the implementation to have the flexibility to either do operations component-by-component, or with a block operation covering all of the bits. We carefully avoid giving a preference in the wording. There is no requirement for the choice to be documented, either, as the implementation can make that choice based on many factors, and could make a different choice for different operations on the same object.

{AI95-00291-02} In the case of a properly aligned, contiguous object whose size is a multiple of the storage unit size, no other bits should be read or updated as part of operating on the object. We don't say this normatively because it would be difficult to normatively define “properly aligned” or “contiguous”.

**Ramification:** Two objects with the same value do not necessarily have the same representation. For example, an implementation might represent False as zero and True as any odd value. Similarly, two objects (of the same type) with the same sequence of bits do not necessarily have the same value. For example, an implementation might use a biased representation in some cases but not others:

```ada
{AI05-0229-1} subtype S is Integer range 1..256;
type A is array(Natural range 1..4) of S
    with Pack;
pragma Pack(A);
X : S := 3;
Y : A := (1, 2, 3, 4);
```

The implementation might use a biased-by-1 representation for the array elements, but not for X. X and Y(3) have the same value, but different representation: the representation of X is a sequence of (say) 32 bits: 0...011, whereas the representation of Y(3) is a sequence of 8 bits: 00000010 (assuming a two's complement representation).

Such tricks are not required, but are allowed.

**Discussion:** The value of any padding bits is not specified by the language, though for a numeric type, it will be much harder to properly implement the predefined operations if the padding bits are not either all zero, or a sign extension.

**Ramification:** {AI05-0229-1} For example, suppose S'Size = 2, and an object X is of subtype S. If the machine code typically uses a 32-bit load instruction to load the value of X, then X'Size should be 32, even though 30 bits of the value are just zeros or sign-extension bits. On the other hand, if the machine code typically masks out those 30 bits, then X'Size should be 2. Usually, such masking only happens for components of a composite type for which Packing, Component_Size, or record layout is specified.

Note, however, that the formal parameter of an instance of Unchecked_Conversion is a special case. Its Size is required to be the same as that of its subtype.

Note that we don't generally talk about the representation of a value. A value is considered to be an amorphous blob without any particular representation. An object is considered to be more concrete.

{AI05-0112-1} {AI05-0295-1} A representation item directly specifies a representation aspect of representation of the entity denoted by the local_name, except in the case of a type-related representation item, whose local_name shall denote a first subtype, and which directly specifies an aspect of the subtype's type. A representation item that names a subtype is either subtype-specific (Size and Alignment clauses) or type-related (all others). [Subtype-specific aspects may differ for different subtypes of the same type.]

**To be honest:** Type-related and subtype-specific are defined likewise for the corresponding aspects of representation.

**To be honest:** Some representation items directly specify more than one aspect.

**Discussion:** {AI05-0229-1} For example, apragma Export (see J.15.5) specifies the convention of an entity, and also specifies that it is exported. **Such items are obsolescent; directly specifying the associated aspects is preferred.**
13.1 Operational and Representation Aspects

8.d **Ramification:** Each specifiable attribute constitutes a separate aspect. An `enumeration_representation_clause` specifies the coding aspect. A `record_representation_clause` (without the `mod_clause`) specifies the record layout aspect. Each representation pragma specifies a separate aspect.

8.e **Reason:** We don't need to say that an `at_clause` or a `mod_clause` specify separate aspects, because these are equivalent to `attribute_definition_clause`s. See J.7, “At Clauses”, and J.8, “Mod Clauses”.

8.e/1/3 `{AI05-0112-1}` We give a default naming for representation aspects of representation pragmas so we don't have to do that for every pragma. Operational and representation attributes are given a default naming in 13.3. We don't want any anonymous aspects; that would make other rules more difficult to write and understand.

8.f **Ramification:** The following representation items are type-related:

- `enumeration_representation_clause`
- `record_representation_clause`
- `Component_Size` clause

8.j/1 *This paragraph was deleted.* `{8652/0009} {AI95-00137-01}` `External_Tag` clause

8.k **Small** clause

8.l **Bit_Order** clause

8.m **Storage_Pool** clause

8.n **Storage_Size** clause

8.n.1/2 `{AI95-00270-01}` `Stream_Size` clause

8.o/1 *This paragraph was deleted.* `{8652/0009} {AI95-00137-01}` `Read` clause

8.p/1 *This paragraph was deleted.* `{8652/0009} {AI95-00137-01}` `Write` clause

8.q/1 *This paragraph was deleted.* `{8652/0009} {AI95-00137-01}` `Input` clause

8.r/1 *This paragraph was deleted.* `{8652/0009} {AI95-00137-01}` `Output` clause

8.s **Machine_Radix** clause

8.t **pragma Pack**

8.u **pragma Import, Export, and Convention** (when applied to a type)

8.v/3 `{AI05-0009-1}` pragmas `Atomic`, `Independent`, and Volatile (when applied to a type)

8.w/3 `{AI05-0009-1}` pragmas `Atomic_Components`, `Independent_Components`, and Volatile_Components (when applied to an array type)

8.x **pragma Discard_Names** (when applied to an enumeration or tagged type)

8.y The following representation items are subtype-specific:

- **Alignment** clause (when applied to a first subtype)

8.z **Size** clause (when applied to a first subtype)

8.aa The following representation items do not apply to subtypes, so they are neither type-related nor subtype-specific:

8.bb 
- **Address** clause (applies to objects and program units)

8.cc 
- **Alignment** clause (when applied to an object)

8.dd 
- **Size** clause (when applied to an object)

8.ee 
- pragmas `Import, Export, and Convention` (when applied to anything other than a type)

8.ff 
- pragmas `Atomic` and Volatile (when applied to an object or a component)

8.gg 
- `{AI05-0009-1}` pragmas `Atomic_Components`, `Independent_Components`, and Volatile_Components (when applied to an array object)

8.hh/3 
- **pragma Discard_Names** (when applied to an exception)

8.ii 
- **pragma Asynchronous** (applies to procedures)

8.jj 
- `{AI95-00414-01}` `pragma No_Return` (applies to subprograms)

8.kk/2 `{AI05-0229-1}` **While an aspect_specification is not a representation item, a similar categorization applies to the aspect that corresponds to each of these representation items (along with aspects that do not have associated representation items).**

8.l/3 `{8652/0009} {AI95-00137-01} {AI05-0183-1}` An operational item directly specifies an operational aspect of the entitytype of the subtype denoted by the `local_name`, except in the case of a type-related operational item, whose `local_name` shall denote a first subtype, and which directly specifies an aspect of
the type of the subtype. The local name of an operational item shall denote a first subtype. An operational item that names a subtype is type-related.

Ramification: \{8652/0009\} AI95-00137-01 The following operational items are type-related:
- External Tag clause
- Read clause
- Write clause
- Input clause
- Output clause

\{AI05-0183-1\} A representation item that directly specifies an aspect of a subtype or type shall appear after the type is completely defined (see 3.11.1), and before the subtype or type is frozen (see 13.14). If a representation item or aspect specification is given that directly specifies an aspect of an entity, then it is illegal to give another representation item or aspect specification that directly specifies the same aspect of the entity.

Ramification: \{8652/0009\} AI95-00137-01 The fact that a representation item (or operational item, see next paragraph) that directly specifies an aspect of an entity is required to appear before the entity is frozen prevents changing the representation of an entity after using the entity in ways that require the representation to be known.

To be honest: \{AI05-0183-1\} The rule preventing multiple specification is also intended to cover other ways to specify representation aspects, such as obsolescent pragma Priority. Priority is not a representation pragma, and as such is neither a representation item nor an aspect specification. Regardless, giving both a pragma Priority and an aspect specification for Priority is illegal. We didn't want to complicate the wording solely to support obsolescent features.

\{8652/0009\} AI95-00137-01 A representation item that directly specifies an aspect of an entity shall appear before the entity is frozen (see 13.14). If an operational item or aspect specification is given that directly specifies an aspect of an entity, then it is illegal to give another operational item or aspect specification that directly specifies the same aspect of the entity.

Ramification: Unlike representation items, operational items can be specified on partial views. Since they don't affect the representation, the full declaration need not be known to determine their legality.

\{AI05-0106-1\} \{AI05-0295-1\} Unless otherwise specified, it is illegal to specify an operational or representation aspect of a generic formal parameter.

Reason: Specifying an aspect on a generic formal parameter implies an added contract for a generic unit. That contract needs to be defined via generic parameter matching rules, and, as aspects vary widely, that has to be done for each such aspect. Since most aspects do not need this complexity (including all language-defined aspects as of this writing), we avoid the complexity by saying that such contract-forming aspect specifications are banned unless the rules defining them explicitly exist. Note that the method of specification does not matter: aspect specifications, representation items, and operational items are all covered by this (and similar) rules.

\{AI05-0295-1\} For an untagged derived type, it is illegal to specify an aspect-related representation items are allowed if the parent type is a by-reference type, or has any user-defined primitive subprograms.

Ramification: \{8652/0009\} AI95-00137-01 \{AI05-0295-1\} On the other hand, subtype-specific representation aspects may be specified for the first subtype of such a type, as can operational aspects.

Reason: \{AI05-0229-1\} \{AI05-0295-1\} The reason for forbidding specification of type-related representation aspects on untagged by-reference types is because a change of representation is impossible when passing by reference (to an inherited subprogram). The reason for forbidding specification of type-related representation aspects on untagged types with user-defined primitive subprograms was to prevent implicit change of representation for type-related aspects of representation upon calling inherited subprograms, because such changes of representation are likely to be expensive at run time. Changes of subtype-specific representation attributes, however, are likely to be cheap. This rule is not needed for tagged types, because other rules prevent a type-related representation aspect from changing the representation of the parent part; we want to allow specifying a type-related representation aspect on a type extension to specify aspects of the extension part. For example, specifying aspect pragma Pack will cause packing of the extension part, but not of the parent part.
Operational and representation aspects of a generic formal parameter are the same as those of the actual. Operational and representation aspects of a partial view are the same for all views of a type as those of the full view. Specification of a type-related representation aspect item is not allowed for a descendant of a generic formal untagged type.

**Ramification:** Since it is not known whether a formal type has user-defined primitive subprograms, specifying type-related representation aspect items for them is not allowed, unless they are tagged (in which case only the extension part is affected in any case).

**Reason:** Since it is not known whether a formal type has user-defined primitive subprograms, specifying type-related representation aspect items for them is not allowed, unless they are tagged (in which case only the extension part is affected in any case).

**Ramification:** All views of a type, including the incomplete and partial views, have the same operational and representation aspects. That's important so that the properties don't change when changing views. While most aspects are not available for an incomplete view, we don't want to leave any holes by not saying that they are the same.

**Reason:** However, this does not apply to objects. Different views of an object can have different representation aspects. For instance, an actual object passed by reference and the associated formal parameter may have different values for Alignment even though the formal parameter is merely a view of the actual object. This is necessary to maintain the language design principle that Alignments are always known at compile time.

**Ramification:** The specification of a representation item that specifies the Size aspect for a given subtype, or the size or storage place for an object (including a component) of a given subtype, shall allow for enough storage space to accommodate any value of the subtype.

**Reason:** If a specification of a representation or operational aspect item that is not supported by the implementation, it is illegal, or raises an exception at run time.

**Reason:** A type declaration is illegal if it has one or more progenitors, and a nonconfirming value was specified for a representation aspect item applied to an ancestor, and this representation item conflicts with the representation of some other ancestor. The cases that cause conflicts are implementation defined.

**Reason:** This rule is needed because it may be the case that only the combination of types in a type declaration causes a conflict. Thus it is not possible, in general, to reject the original representation item or aspect specification. For instance:

```ada
package Pkg1 is
  type Ifc is interface;
  type T is tagged record
    Fld : Integer;
  end record;
  for T use record
    Fld at 0 range 0 .. Integer'Size - 1;
  end record;
end Pkg1;
```

Assume the implementation uses a single tag with a default offset of zero, and that it allows the use of nondefault locations for the tag (and thus accepts representation items like the one above). The representation item will force a nondefault location for the tag (by putting a component other than the tag into the default location). Clearly, this package will be accepted by the implementation. However, other declarations could cause trouble. For instance, the implementation could reject:

```ada
with Pkg1;
package Pkg2 is
  type NewT is new Pkg1.T and Pkg1.Ifce with null record;
end Pkg2;
```

because the declarations of T and Ifc have a conflict in their representation items. This is clearly necessary (it's hard to imagine how Ifc'Class could work with the tag at a location other than the one it is expecting without introducing distributed overhead).
Conflicts will usually involve implementation-defined attributes (for specifying the location of the tag, for instance), although the example above shows that doesn't have to be the case. For this reason, we didn't try to specify exactly what causes a conflict; it will depend on the implementation's implementation model and what representation aspect items it allows to be changed.

Implementation Note: An implementation can only use this rule to reject type declaration where one of its ancestors had a nonconfirming representation value specified. An implementation must ensure that the default representations of ancestors cannot conflict.

Static Semantics

If two subtypes statically match, then their subtype-specific aspects (Size and Alignment) are the same.

Reason: This is necessary because we allow (for example) conversion between access types whose designated subtypes statically match. Note that most aspects (including the subtype-specific aspects Size and Alignment) may not be specified for a nonfirst subtype. The only language-defined exceptions to this rule are the Static Predicate and Dynamic Predicate aspects; it is illegal to specify an aspect (including a subtype-specific one) for a nonfirst subtype.

Consider, for example:

```ada
package P1 is
  subtype S1 is Integer range 0..2**16-1;
  for S1'Size use 16; -- Illegal!
  -- S1'Size would be 16 by default.
  type A1 is access all S1;
  X1: A1;
end P1;

package P2 is
  subtype S2 is Integer range 0..2**16-1;
  for S2'Size use 32; -- Illegal!
  type A2 is access all S2;
  X2: A2;
end P2;

procedure Q is
  use P1, P2;
  type Array1 is array(Integer range <>) of aliased S1
    with Pack;
    pragma Pack(Array1);
  Obj1: Array1(1..100);
  type Array2 is array(Integer range <>) of aliased S2
    with Pack;
    pragma Pack(Array2);
  Obj2: Array2(1..100);
begin
  X1 := Obj2(17)'Unchecked_Access;
  X2 := Obj1(17)'Unchecked_Access;
end Q;
```

Loads and stores through X1 would read and write 16 bits, but X1 points to a 32-bit location. Depending on the endianness of the machine, loads might load the wrong 16 bits. Stores would fail to zero the other half in any case.

Loads and stores through X2 would read and write 32 bits, but X2 points to a 16-bit location. Thus, adjacent memory locations would be trashed.

Hence, the above is illegal. Furthermore, the compiler is forbidden from choosing different Sizes by default, for the same reason.

The same issues apply to Alignment.
Each aspect of representation of an entity is as follows:

- If the aspect is specified for the entity, meaning that it is either directly specified or inherited, then that aspect of the entity is as specified, except in the case of Storage_Size, which specifies a minimum.

  Ramification: This rule implies that queries of the aspect return the specified value. For example, if the user writes "for X'Size use 32;", then a query of X'Size will return 32.

- If an aspect of representation of an entity is not specified, it is chosen by default in an unspecified manner.

  Ramification: The rules forbid things like “for S'BaseAlignment use ...” and “for S'Base use record ...”.

Discussion: The intent is that implementations will represent the components of a composite value in the same way for all subtypes of a given composite type. Hence, Component_Size and record layout are type-related aspects.

Ramification: As noted previously, in the case of an object, the entity mentioned in this text is a specific view of an object. That means that only references to the same view of an object that has a specified value for a representation aspect R necessarily have that value for the aspect R. The values of the aspect R for a different view of that object is unspecified. In particular, this means that the representation values for by-reference parameters is unspecified; they do not have to be the same as those of the underlying object.

Ramification: If an inherited aspect is confirmed by an aspect specification or a later representation item for a derived type, the confirming specification does not override the inherited one. Thus the derived type has both a specified confirming value and an inherited nonconfirming representation value — this means that rules that apply only to nonconfirming representation values still apply to this type.

In contrast, whether operational aspects are inherited by an untagged derived type depends on each specific aspect; unless specified, an operational aspect is not inherited. [Operational aspects are never inherited for a tagged type.] When operational aspects are inherited by an untagged derived type, aspects that were directly specified by aspect specifications or operational items that are visible at the point before the declaration of the derived type declaration, or (in the case where the parent is derived) that were inherited by the parent type from the grandparent type are inherited. An inherited operational aspect is overridden by a subsequent aspect specification or operational item that specifies the same aspect of the type.

Reason: This defines the parameter names and types, and the needed implicit conversions.

To be honest: A record_representation_clause for a record extension does not override the layout of the parent part; if the layout was specified for the parent type, it is inherited by the record extension.
An aspect specification or a representation item that specifies an aspect of representation that would have been chosen in the absence of the aspect specification or representation item is said to be confirming. The aspect value specified in this case is said to be a confirming representation aspect value. Other values of the aspect are said to be nonconfirming, as are the aspect specifications and representation items that specified them.

Dynamic Semantics

For the elaboration of an aspect clause, a representation clause, any evaluable constructs within it are evaluated.

Ramification: Elaboration of representation pragmas is covered by the general rules for pragmas in 2.8 Section 2.

Implementation Permissions

An implementation may interpret aspects of representation aspects in an implementation-defined manner. An implementation may place implementation-defined restrictions on the specification of representation aspects items. A recommended level of support is defined specified for the specification of representation aspects items and related features in each subclause. These recommendations are changed to requirements for implementations that support the Systems Programming Annex (see C.2, “Required Representation Support”).

Implementation defined: The interpretation of each aspect of representation aspect.

Implementation defined: Any restrictions placed upon the specification of representation aspects items.

Ramification: Implementation-defined restrictions may be enforced either at compile time or at run time. There is no requirement that an implementation justify any such restrictions. They can be based on avoiding implementation complexity, or on avoiding excessive inefficiency, for example.

There is no such permission for operational aspects.

Implementation Advice

The recommended level of support for the specification of all representation aspects items is qualified as follows:

• A confirming specification for a representation aspect item should be supported.

To be honest: A confirming representation aspect value item might not be possible for some entities. For instance, consider an unconstrained array. The size of such a type is implementation-defined, and might not actually be a representable value, or might not be static.

• An implementation need not support the specification for a representation aspect that contains items containing nonstatic expressions, unless except that an implementation should support a representation item for a given entity if each nonstatic expression in the representation item is a name that statically denotes a constant declared before the entity.

Reason: This is to avoid the following sort of thing:

```ada
X : Integer := P(...);
Y : Address := G(...);
for X'Address use Y;
```

In the above, we have to evaluate the initialization expression for X before we know where to put the result. This seems like an unreasonable implementation burden.

The above code should instead be written like this:

```ada
Y : constant Address := G(...);
X : Integer := P(...);
for X'Address use Y;
```

This allows the expression “Y” to be safely evaluated before X is created.

The constant could be a formal parameter of mode in.
An implementation can support other nonstatic expressions if it wants to. Expressions of type Address are hardly ever static, but their value might be known at compile time anyway in many cases.

- An implementation need not support a specification for the Size for a given composite subtype, nor the size or storage place for an object (including a component) of a given composite subtype, unless the constraints on the subtype and its composite subcomponents (if any) are all static constraints.

- {AI95-00291-02} {AI05-0295-1} An implementation need not support specifying a nonconfirming representation aspect value if it could cause an aliased object or an object of a by-reference type to be allocated at a nonaddressable location or, when the alignment attribute of the subtype of such an object is nonzero, at an address that is not an integral multiple of that alignment. An aliased component, or a component whose type is by-reference, should always be allocated at an addressable location.

  **Reason:** The intent is that access types, type System.Address, and the pointer used for a by-reference parameter should be implementable as a single machine address — bit-field pointers should not be required. (There is no requirement that this implementation be used — we just want to make sure it's feasible.)

  **Implementation Note:** {AI95-00291-02} We want subprograms to be able to assume the properties of the types of their parameters inside of subprograms. While many objects can be copied to allow this (and thus do not need limitations), aliased or by-reference objects cannot be copied (their memory location is part of their identity). Thus, note that the above rule does not apply to types that merely allow by-reference parameter passing; for such types, a copy typically needs to be made at the call site when a bit-aligned component is passed as a parameter.

- {AI95-00291-02} {AI05-0295-1} An implementation need not support specifying a nonconfirming representation aspect value if it could cause an aliased object of an elementary type to have a size other than that which would have been chosen by default.

  **Reason:** Since all bits of elementary objects participate in operations, aliased objects must not have a different size than that assumed by users of the access type.

- {AI95-00291-02} {AI05-0295-1} An implementation need not support specifying a nonconfirming representation aspect value if it could cause an aliased object of a composite type, or an object whose type is by-reference, to have a size smaller than that which would have been chosen by default.

  **Reason:** Unlike elementary objects, there is no requirement that all bits of a composite object participate in operations. Thus, as long as the object is the same or larger in size than that expected by the access type, all is well.

  **Ramification:** This rule presumes that the implementation allocates an object of a size specified to be larger than the default size in such a way that access of the default size suffices to correctly read and write the value of the object.

- {AI95-00291-02} {AI05-0295-1} An implementation need not support specifying a nonconfirming subtype-specific representation aspect value for a type with this representation in an indefinite or abstract subtype.

  **Reason:** {AI05-0295-1} Representation aspects are often not well-defined for such types.

  **Ramification:** {AI95-00291-02} {AI05-0229-1} A type with the Pack aspect specified will typically not be packed so tightly as to disobey the above rule. A Component_Size clause or record_representation_clause will typically be illegal if it disobeys the above rule. Atomic components have similar restrictions (see C.6, “Shared Variable Control”).

- {AI95-00291-02} {AI05-0295-1} For purposes of these rules, the determination of whether specifying a representation aspect value for a type could cause an object to have some property is based solely on the properties of the type itself, not on any available information about how the type is used. In particular, it presumes that minimally aligned objects of this type might be declared at some point.

  **Implementation Advice:** The recommended level of support for all representation items should be followed.

NOTES

1 {AI05-0229-1} Aspects that can be specified are defined throughout this International Standard, and are summarized in K.1.
Incompatibilities With Ada 83

It is now illegal for a representation item to cause a derived by-reference type to have a different record layout from its parent. This is necessary for by-reference parameter passing to be feasible. This only affects programs that specify the representation of types derived from types containing tasks; most by-reference types are new to Ada 95. For example, if A1 is an array of tasks, and A2 is derived from A1, it is illegal to apply a pragma Pack to A2.

Extensions to Ada 83

{8652/0009} {AI95-00137-01} Ada 95 allows additional aspect clauses for objects.

29.a

Wording Changes from Ada 83

{8652/0009} {AI95-00137-01} The syntax rule for type_representation_clause is removed; the right-hand side of that rule is moved up to where it was used, in aspect_clause. There are two references to “type representation clause” in RM83, both in Section 13; these have been reworded. Also, the aspect_clause has been renamed the aspect_clause to reflect that it can be used to control more than just representation aspects.

29.c

{8652/0009} {AI95-00137-01} {AI95-00114-01} We have defined a new term “representation item,” which includes all representation clauses and representation pragmas, as well as component_clauses. This is convenient because the rules are almost identical for all of them. We have also defined the new terms “operational item” and “operational aspects” in order to conveniently handle new types of specifiable entities.

29.d

All of the forcing occurrence stuff has been moved into its own subclause (see 13.14), and rewritten to use the term “freezing”.

RM83-13.1(10) requires implementation-defined restrictions on representation items to be enforced at compile time. However, that is impossible in some cases. If the user specifies a junk (nonstatic) address in an address clause, and the implementation chooses to detect the error (for example, using hardware memory management with protected pages), then it's clearly going to be a run-time error. It seems silly to call that “semantics” rather than “a restriction.”

29.f

RM83-13.1(10) tries to pretend that representation clauses don't affect the semantics of the program. One counter-example is the Small clause. Ada 95 has more counter-examples. We have noted the opposite above.

RM83 requires that operational items are defined, and the recommended level of support is now that they always be supported.

29.g

Some of the more stringent requirements are moved to C.2, “Required Representation Support”.

29.h

Extensions to Ada 95

{AI95-00291-02} Amendment Correction: Confirming representation items are defined, and the recommended level of support is now that they always be supported.

29.i

Wording Changes from Ada 95

{8652/0009} {AI95-00137-01} Corrigendum: Added operational items in order to eliminate unnecessary restrictions and permissions on stream attributes. As part of this, representation_clause was renamed to aspect_clause.

29.j

{8652/0009} {AI95-00137-01} {AI95-00326-01} Corrigendum: Added wording to say that the partial and full views have the same operational and representation aspects. Ada 2005 extends this to cover all views, including the incomplete view.

29.k

{8652/0040} {AI95-00108-01} Corrigendum: Changed operational items to have inheritance specified for each such aspect.

29.l

{AI95-00251-01} Added wording to allow the rejection of types with progenitors that have conflicting representation items.

29.m

{AI95-00291-02} The description of the representation of an object was clarified (with great difficulty reaching agreement). Added wording to say that representation items on aliased and by-reference objects never need be supported if they would not be implementable without distributed overhead even if other recommended level of support says otherwise. This wording matches the rules with reality.

29.n

{AI95-00444-01} {AI95-00055-1} Added wording so that inheritance depends on whether operational items are visible rather than whether they occur before the declaration (we don't want to look into private parts). Also limited limited operational inheritance to untagged types to avoid anomalies with private extensions (this is not incompatible, no existing operational attribute used this capability). Also added wording to clearly define that subprogram inheritance works like derivation of subprograms.

29.o

Incompatibilities With Ada 2005

{AI05-0106-1} Correction: Specifying a language-defined aspect for a generic formal parameter is no longer allowed. Most aspects could not be specified on these anyway; moreover, this was not allowed in Ada 83, so it is unlikely that
compilers are supporting this as a capability (and it is not likely that they have a consistent definition of what it means if it is allowed). Thus, we expect this to occur rarely in existing programs.

Wording Changes from Ada 2005

{AI05-0009-1} Correction: Defined that overriding of a representation aspect only happens for a nonconfirming representation item. This prevents a derived type from being considered to have only a confirming representation item when the value would be nonconfirming if given on a type that does not inherit any aspects of representation. This change just eliminates a wording confusion and ought not change any behavior.

{AI05-0112-1} Correction: Defined a default naming for representation aspects that are representation pragmas.

{AI05-0183-1} Added text ensuring that the rules for representational and operational items also apply appropriately to aspect specifications; generalized operational aspects so that they can be defined for entities other than types. Any extensions are documented elsewhere.

{AI05-0295-1} Rewrote many rules to be in terms of "specifying a representation aspect" rather than use of a "representation item". This better separates how an aspect is specified from what rules apply to the value of the aspect.

### 13.1.1 Aspect Specifications

{AI05-0183-1} [Certain representation or operational aspects of an entity may be specified as part of its declaration using an aspect specification, rather than using a separate representation or operational item.] The declaration with the aspect specification is termed the associated declaration.

### Syntax

{AI05-0183-1} aspect_specification ::= 
  with aspect_mark [=> aspect_definition] [, 
  aspect_mark [=> aspect_definition] ]

{AI05-0183-1} aspect_mark ::= aspect_identifier[’Class]

{AI05-0183-1} aspect_definition ::= name | expression | identifier

### Language Design Principles

{AI05-0183-1} {AI05-0267-1} The aspect specification is an optional element in most kinds of declarations. Here is a list of all kinds of declarations and an indication of whether or not they allow aspect clauses, and in some cases a short discussion of why (* = allowed, NO = not allowed). Kinds of declarations with no indication are followed by their subdivisions (which have indications).

```
basic_declaration
  type_declaration
  full_type_declaration
  type_declaration_syntax*
  task_type_declaration*
  protected_type_declaration*
  incomplete_type_declaration -- NO
  -- Incomplete type aspects cannot be read by an attribute or specified by attribute_definition_clauses
  -- (the attribute name is illegal), so it would not make sense to allow this in another way.
  private_type_declaration*
  private_extension_declaration*
  subtype_declaration*
  object_declaration
  object_declaration_syntax*
  single_task_declaration*
  single_protected_declaration*
  number_declaration -- NO
  subprogram_declaration*

{AI05-0267-1} Syntactically, aspect_specifications generally are located at the end of declarations. When a 
declaration is all in one piece such as a null_procedure_declaration, object_declaration, or generic_instantiation the 
aspect_specification goes at the end of the declaration; it is then more visible and less likely to interfere with the 
layout of the rest of the structure. However, we make an exception for program units (other than subprogram 
specifications) and bodies, in which the aspect_specification goes before the is. In these cases, the entity could be 
large and could contain other declarations that also have aspect_specifications, so it is better to put the 
aspect_specification toward the top of the declaration. (Some aspects – such as Pure – also affect the legality of the 
contents of a unit, so it would be annoying to only see those after reading the entire unit.)

Name Resolution Rules

{AI05-0183-1} An aspect_mark identifies an aspect of the entity defined by the associated declaration 
(the associated entity); the aspect denotes an object, a value, an expression, a subprogram, or some other 
kind of entity. If the aspect_mark identifies:

- an aspect that denotes an object, the aspect_definition shall be a name. The expected type for the 
  name is the type of the identified aspect of the associated entity;
- an aspect that is a value or an expression, the aspect_definition shall be an expression. The 
  expected type for the expression is the type of the identified aspect of the associated entity;
- an aspect that denotes a subprogram, the aspect_definition shall be a name; the expected profile 
  for the name is the profile required for the aspect of the associated entity;
- an aspect that denotes some other kind of entity, the aspect_definition shall be a name, and the 
  name shall resolve to denote an entity of the appropriate kind;
an aspect that is given by an identifier specific to the aspect, the aspect definition shall be an identifier, and the identifier shall be one of the identifiers specific to the identified aspect.

The usage names in an aspect definition are not resolved at the point of the associated declaration, but rather are resolved at the end of the immediately enclosing declaration list.

If the associated declaration is for a subprogram or entry, the names of the formal parameters are directly visible within the aspect definition, as are certain attributes, as specified elsewhere in this International Standard for the identified aspect. If the associated declaration is a type declaration, within the aspect definition the names of any components are directly visible, and the name of the first subtype denotes the current instance of the type (see 8.6). If the associated declaration is a subtype declaration, within the aspect definition the name of the new subtype denotes the current instance of the subtype.

Legality Rules

If the first freezing point of the associated entity comes before the end of the immediately enclosing declaration list, then each usage name in the aspect definition shall resolve to the same entity at the first freezing point as it does at the end of the immediately enclosing declaration list.

At most one occurrence of each aspect mark is allowed within a single aspect specification. The aspect identified by the aspect mark shall be an aspect that can be specified for the associated entity (or view of the entity defined by the associated declaration).

The aspect definition associated with a given aspect mark may be omitted only when the aspect mark identifies an aspect of a boolean type, in which case it is equivalent to the aspect definition being specified as True.

If the aspect mark includes 'Class, then the associated entity shall be a tagged type or a primitive subprogram of a tagged type.

There are no language-defined aspects that may be specified on a renaming declaration, a generic formal parameter declaration, a subunit, a package body, a task body, a protected body, or a body stub other than a subprogram body stub.

Discussion: Implementation-defined aspects can be allowed on these, of course; the implementation will need to define the semantics. In particular, the implementation will need to define actual type matching rules for any aspects allowed on formal types; there are no default matching rules defined by the language.

A language-defined aspect shall not be specified in an aspect specification given on a subprogram body or subprogram body stub that is a completion of another declaration.

Reason: Most language-defined aspects (for example, preconditions) are intended to be available to callers, and specifying them on a body that has a separate declaration hides them from callers. Specific language-defined aspects may allow this, but they have to do so explicitly (by defining an alternative Legality Rule), and provide any needed rules about visibility. Note that this rule does not apply to implementation-defined aspects, so implementers need to carefully define whether such aspects can be applied to bodies and stubs, and what happens if they are specified on both the declaration and body of a unit.

Static Semantics

Depending on which aspect is identified by the aspect mark, an aspect definition specifies:

- a name that denotes a subprogram, object, or other kind of entity;
- an expression, which is either evaluated to produce a single value, or which (as in a precondition) is to be evaluated at particular points during later execution; or
- an identifier specific to the aspect.
The identified aspect of the associated entity, or in some cases, the view of the entity defined by the declaration, is as specified by the aspect definition (or by the default of True when boolean). Whether an aspect specification applies to an entity or only to the particular view of the entity defined by the declaration is determined by the aspect mark and the kind of entity. The following aspects are view specific:

- An aspect specified on an object_declaration;
- An aspect specified on a subprogram_declaration;
- An aspect specified on a renaming_declaration.

All other aspect_specifications are associated with the entity, and apply to all views of the entity, unless otherwise specified in this International Standard.

If the aspect_mark includes 'Class, then:
- if the associated entity is a tagged type, the specification applies to all descendants of the type;
- if the associated entity is a primitive subprogram of a tagged type T, the specification applies to the corresponding primitive subprogram of all descendants of T.

All specifiable operational and representation attributes may be specified with an aspect_specification instead of an attribute_definition_clause (see 13.3).

Ramification: The name of the aspect is the same as that of the attribute (see 13.3), so the aspect_mark is the attribute_designator of the attribute.

Any aspect specified by a representation pragma or library unit pragma that has a local_name as its single argument may be specified by an aspect_specification, with the entity being the local_name. The aspect_definition is expected to be of type Boolean. The expression shall be static.

Ramification: The name of the aspect is the same as that of the pragma (see 13.1), so the aspect_mark is the name of the pragma.

In addition, other operational and representation aspects not associated with specifiable attributes or representation pragmas may be specified, as specified elsewhere in this International Standard.

If an aspect of a derived type is inherited from an ancestor type and has the boolean value True, the inherited value shall not be overridden to have the value False for the derived type, unless otherwise specified in this International Standard.

If a Legality Rule or Static Semantics rule only applies when a particular aspect has been specified, the aspect is considered to have been specified only when the aspect_specification or attribute_definition_clause is visible (see 8.3) at the point of the application of the rule.

Reason: Some rules only apply when an aspect has been specified (for instance, an indexable type is one that has aspect Variable_Indexing specified). In order to prevent privacy breaking, this can only be true when the specification of the aspect is visible. In particular, if the Variable_Indexing aspect is specified on the full view of a private type, the private type is not considered an indexable type.

Alternative legality and semantics rules may apply for particular aspects, as specified elsewhere in this International Standard.

Dynamic Semantics

At the freezing point of the associated entity, the aspect_specification is elaborated. The elaboration of the aspect_specification includes the evaluation of the name or expression, if any, unless the aspect itself is an expression. If the corresponding aspect represents an expression (as in a precondition), the elaboration has no effect; the expression is evaluated later at points within the execution as specified elsewhere in this International Standard for the particular aspect.
Implementation Permissions

Implementations may support implementation-defined aspects. The aspect specification for an implementation-defined aspect may use an implementation-defined syntax for the aspect definition, and may follow implementation-defined legality and semantics rules.

Discussion: The intent is to allow implementations to support aspects that are defined, for example, by a subtype indication rather than an expression or a name. We chose not to try to enumerate all possible aspect definition syntaxes, but to give implementations maximum freedom. Unrecognized aspects are illegal whether or not they use custom syntax, so this freedom does not reduce portability.

Implementation defined: Implementation-defined aspects, including the syntax for specifying such aspects and the legality rules for such aspects.

Extensions to Ada 2005

Aspect specifications are new.

13.2 Packed Types

Pragma Pack

The Pack aspect having the value True, pragma Pack specifies that storage minimization should be the main criterion when selecting the representation of a composite type.

Paragraphs 2 through 4 were moved to Annex J, “Obsolescent Features”.

Syntax

The form of a pragma Pack is as follows:

```
pragma Pack(first_subtype_local_name);
```

Legality Rules

The first_subtype_local_name of a pragma Pack shall denote a composite subtype.

Static Semantics

For a full type declaration of a composite type, the following language-defined representation aspect may be specified: A pragma Pack specifies the packing aspect of representation; the type (or the extension part) is said to be packed. For a type extension, the parent part is packed as for the parent type, and a pragma Pack causes packing only of the extension part.

Pack

The type of aspect Pack is Boolean. When aspect Pack is True for a type, the type (or the extension part) is said to be packed. For a type extension, the parent part is packed as for the parent type, and specifying Pack causes packing only of the extension part.

Aspect Description for Pack: Minimize storage when laying out records and arrays.

If directly specified, the aspect definition shall be a static expression. If not specified (including by inheritance), the aspect is False.

Ramification: The only high level semantic effect of specifying the pragma Pack aspect is potential loss of independent addressability (see 9.10, “Shared Variables”).

Implementation Advice

If a type is packed, then the implementation should try to minimize storage allocated to objects of the type, possibly at the expense of speed of accessing components, subject to reasonable complexity in addressing calculations.

Implementation Advice: Storage allocated to objects of a packed type should be minimized.
Ramification: \{AI05-0229-1\} Specifying the \texttt{pragma} Pack aspect is for gaining space efficiency, possibly at the expense of time. If more explicit control over representation is desired, then a record_representation_clause, a Component_Size clause, or a Size clause should be used instead of, or in addition to, the \texttt{pragma} Pack aspect.

\{AI95-00291-02\} If a packed type has a component that is not of a by-reference type and has no aliased part, then such a component need not be aligned according to the Alignment of its subtype; in particular it need not be allocated on a storage element boundary.

\{AI05-0229-1\} The recommended level of support for the \texttt{pragma} Pack aspect is:

- For a packed record type, the components should be packed as tightly as possible subject to the Sizes of the component subtypes, and subject to any record_representation_clause that applies to the type; the implementation may, but need not, reorder components or cross aligned word boundaries to improve the packing. A component whose Size is greater than the word size may be allocated an integral number of words.

  Ramification: The implementation can always allocate an integral number of words for a component that will not fit in a word. The rule also allows small component sizes to be rounded up if such rounding does not waste space. For example, if Storage_Unit = 8, then a component of size 8 is probably more efficient than a component of size 7 plus a 1-bit gap (assuming the gap is needed anyway).

- \{AI05-0009-1\} For a packed array type, if the component subtype’s Size of the component subtype is less than or equal to the word size, and Component_Size is not specified for the type, Component_Size should be less than or equal to the Size of the component subtype, rounded up to the nearest factor of the word size.

  Ramification: If a component subtype is aliased, its Size will generally be a multiple of Storage_Unit, so it probably won’t get packed very tightly.

  Implementation Advice: The recommended level of support for the \texttt{pragma} Pack aspect should be followed.

Wording Changes from Ada 95

\{AI95-00291-02\} \{AI05-0229-1\} Added clarification that the \texttt{pragma} Pack aspect can ignore alignment requirements on types that don't have by-reference or aliased parts. This was always intended, but there was no wording to that effect.

Extensions to Ada 2005

\{AI05-0229-1\} Aspect Pack is new; \texttt{pragma} Pack is now obsolescent.

Wording Changes from Ada 2005

\{AI05-0009-1\} Correction: Fixed so that the presence or absence of a confirming Component_Size representation clause does not change the meaning of the Pack aspect.

13.3 \textbf{Operational and Representation Attributes}

\{8652/0009\} \{AI95-00137-01\} [ The values of certain implementation-dependent characteristics can be obtained by interrogating appropriate operational or representation attributes. Some of these attributes are specifiable via an attribute_definition_clause.]

Language Design Principles

In general, the meaning of a given attribute should not depend on whether the attribute was specified via an attribute_definition_clause, or chosen by default by the implementation.

Syntax

attribute_definition_clause ::= for local_name\attribute_designator use expression;
| for local_name\attribute_designator use name;
Name Resolution Rules

3 For an attribute_definition_clause that specifies an attribute that denotes a value, the form with an expression shall be used. Otherwise, the form with a name shall be used.

4 For an attribute_definition_clause that specifies an attribute that denotes a value or an object, the expected type for the expression or name is that of the attribute. For an attribute_definition_clause that specifies an attribute that denotes a subprogram, the expected profile for the name is the profile required for the attribute. For an attribute_definition_clause that specifies an attribute that denotes some other kind of entity, the name shall resolve to denote an entity of the appropriate kind.

4.a Ramification: For example, the Size attribute is of type universal_integer. Therefore, the expected type for Y in “for X'Size use Y;” is universal_integer, which means that Y can be of any integer type.

4.b Discussion: For attributes that denote subprograms, the required profile is indicated separately for the individual attributes.

4.c Ramification: For an attribute_definition_clause with a name, the name need not statically denote the entity it denotes. For example, the following kinds of things are allowed:

   for Some_Access_Type'Storage_Pool use Storage_Pool_Array(I);
   for Some_Type'Read use Subprogram_Pointer.all;

5/3 \{8652/0009\} \{AI95-00137-01\} \{AI05-0183-1\} An attribute_designator is allowed in an attribute_definition_clause only if this International Standard explicitly allows it, or for an implementation-defined attribute if the implementation allows it. Each specifiable attribute constitutes an operational aspect or aspect of representation; the name of the aspect is that of the attribute.

5.a Discussion: For each specifiable attribute, we generally say something like, “The ... attribute may be specified for ... via an attribute_definition_clause.”

5.b The above wording allows for T'Class'Alignment, T'Class'Size, T'Class'Input, and T'Class'Output to be specifiable.

5.c A specifiable attribute is not necessarily specifiable for all entities for which it is defined. For example, one is allowed to ask T'Component_Size for an array subtype T, but “for T'Component_Size use ...” is only allowed if T is a first subtype, because Component_Size is a type-related aspect.

6 For an attribute_definition_clause that specifies an attribute that denotes a subprogram, the profile shall be mode conformant with the one required for the attribute, and the convention shall be Ada. Additional requirements are defined for particular attributes.

6.a Ramification: This implies, for example, that if one writes:

   for T'Read use R;

6.b R has to be a procedure with two parameters with the appropriate subtypes and modes as shown in 13.13.2.

Static Semantics

7/2 \{AI95-00270-01\} A Size clause is an attribute_definition_clause whose attribute_designator is Size. Similar definitions apply to the other specifiable attributes.

7.a To be honest: An attribute_definition_clause is type-related or subtype-specific if the attribute_designator denotes a type-related or subtype-specific attribute, respectively.

8 A storage element is an addressable element of storage in the machine. A word is the largest amount of storage that can be conveniently and efficiently manipulated by the hardware, given the implementation's run-time model. A word consists of an integral number of storage elements.

8.a Discussion: A storage element is not intended to be a single bit, unless the machine can efficiently address individual bits.

8.b Ramification: For example, on a machine with 8-bit storage elements, if there exist 32-bit integer registers, with a full set of arithmetic and logical instructions to manipulate those registers, a word ought to be 4 storage elements — that is, 32 bits.
Discussion: The “given the implementation's run-time model” part is intended to imply that, for example, on an 80386 running MS-DOS, the word might be 16 bits, even though the hardware can support 32 bits.

A word is what ACID refers to as a “natural hardware boundary”.

Storage elements may, but need not be, independently addressable (see 9.10, “Shared Variables”). Words are expected to be independently addressable.

{AI95-00133-01} {AI05-0092-1} A machine scalar is an amount of storage that can be conveniently and efficiently loaded, stored, or operated upon by the hardware. Machine scalars consist of an integral number of storage elements. The set of machine scalars is implementation defined, but includes at least the storage element and the word. Machine scalars are used to interpret component clauses when the nondefault bit ordering applies.

Implementation defined: The set of machine scalars.

Ramification: {AI05-0092-1} A single storage element is a machine scalar in all Ada implementations. Similarly, a word is a machine scalar in all implementations (although it might be the same as a storage element). An implementation may define other machine scalars that make sense on the target (a half-word, for instance).

{8652/0009} {AI95-00137-01} {AI05-0191-1} The following representation attributes are defined: Address, Alignment, Size, Storage Size, and Component Size, Has Same Storage, and Overlaps Storage. The following attributes are defined:

For a prefix X that denotes an object, program unit, or label:

X'Address Denotes the address of the first of the storage elements allocated to X. For a program unit or label, this value refers to the machine code associated with the corresponding body or statement. The value of this attribute is of type System.Address.

Ramification: Here, the “first of the storage elements” is intended to mean the one with the lowest address; the endianness of the machine doesn't matter.

{AI05-0095-1} The prefix of X'Address shall not statically denote a subprogram that has convention Intrinsic. X'Address raises Program Error if X denotes a subprogram that has convention Intrinsic.

Address may be specified for stand-alone objects and for program units via an attribute_definition_clause.

Ramification: Address is not allowed for enumeration literals, predefined operators, derived task types, or derived protected types, since they are not program units.

Address is not allowed for intrinsic subprograms, either. That can be checked statically unless the prefix is a generic formal subprogram and the attribute reference is in the body of a generic unit. We define that case to raise Program_Error, in order that the compiler does not have to build a wrapper for intrinsic subprograms.

The validity of a given address depends on the run-time model; thus, in order to use Address clauses correctly, one needs intimate knowledge of the run-time model.

{AI05-0229-1} If the Address of an object is specified, any explicit or implicit initialization takes place as usual, unless the pragma Import aspect is also specified for the object (in which case any necessary initialization is presumably done in the foreign language).

Any compilation unit containing an attribute_reference of a given type depends semantically on the declaration of the package in which the type is declared, even if not mentioned in an applicable with_clause — see 10.1.1. In this case, it means that if a compilation unit contains X'Address, then it depends on the declaration of System. Otherwise, the fact that the value of Address is of a type in System wouldn't make sense; it would violate the “legality determinable via semantic dependences” Language Design Principle.

AI83-00305 — If X is a task type, then within the body of X, X denotes the current task object; thus, X'Address denotes the object's address.

Interrupt entries and their addresses are described in J.7.1, “Interrupt Entries”.

If X is not allocated on a storage element boundary, X'Address points at the first of the storage elements that contains any part of X. This is important for the definition of the Position attribute to be sensible.

Aspect Description for Address: Machine address of an entity.
Erroneous Execution

{AI05-0009-1} If an Address is specified, it is the programmer's responsibility to ensure that the address is valid and appropriate for the entity and its use; otherwise, program execution is erroneous.

Discussion: “Appropriate for the entity and its use” covers cases such as misaligned addresses, read-only code addresses for variable data objects (and nonexecutable data addresses for code units), and addresses which would force objects that are supposed to be independently addressable to not be. Such addresses may be “valid” as they designate locations that are accessible to the program, but the program execution is still erroneous (meaning that implementations do not have to worry about these cases).

Implementation Advice

For an array X, X'Address should point at the first component of the array, and not at the array bounds.

Implementation Advice: For an array X, X'Address should point at the first component of the array rather than the array bounds.

Ramification: On the other hand, we have no advice to offer about discriminants and tag fields; whether or not the address points at them is not specified by the language. If discriminants are stored separately, then the Position of a discriminant might be negative, or might raise an exception.

The recommended level of support for the Address attribute is:

- X'Address should produce a useful result if X is an object that is aliased or of a by-reference type, or is an entity whose Address has been specified.
  
  Reason: Aliased objects are the ones for which the Unchecked_Access attribute is allowed; hence, these have to be allocated on an addressable boundary anyway. Similar considerations apply to objects of a by-reference type.

- An implementation should support Address clauses for imported subprograms.

- This paragraph was deleted.\{AI95-00291-02\} Objects (including subcomponents) that are aliased or of a by-reference type should be allocated on storage element boundaries.

  This paragraph was deleted. Reason: This is necessary for the Address attribute to be useful (since First_Bit and Last_Bit apply only to components). Implementations generally need to do this anyway, for tasking to work properly.

- If the Address of an object is specified, or it is imported or exported, then the implementation should not perform optimizations based on assumptions of no aliases.

  Implementation Advice: The recommended level of support for the Address attribute should be followed.

NOTES

2 The specification of a link name with the Link_Name aspect in a pragma Export (see B.1) for a subprogram or object is an alternative to explicit specification of its link-time address, allowing a link-time directive to place the subprogram or object within memory.

3 The rules for the Size attribute imply, for an aliased object X, that if X'Size = Storage_Unit, then X'Address points at a storage element containing all of the bits of X, and only the bits of X.

Wording Changes from Ada 83

21.a The intended meaning of the various attributes, and their attribute_definition_clauses, is more explicit.

21.b The address_clause has been renamed to at_clause and moved to Annex J, “Obsolescent Features”. One can use an Address clause (“for T'Address use ...”) instead.

21.c The attributes defined in RM83-13.7.3 are moved to Annex G, A.5.3, and A.5.4.

Wording Changes from Ada 2005

{AI05-0183-1} Defined that the names of aspects are the same as the name of the attribute; that gives a name to use in aspect_specifications (see 13.1.1).
Language Design Principles

By default, the Alignment of a subtype should reflect the “natural” alignment for objects of the subtype on the machine. The Alignment, whether specified or default, should be known at compile time, even though Addresses are generally not known at compile time. (The generated code should never need to check at run time the number of zero bits at the end of an address to determine an alignment).

There are two symmetric purposes of Alignment clauses, depending on whether or not the implementation has control over object allocation. If the implementation allocates an object, the implementation should ensure that the Address and Alignment are consistent with each other. If something outside the implementation allocates an object, the implementation should be allowed to assume that the Address and Alignment are consistent, but should not assume stricter alignments than that.

Static Semantics

{AI95-00291-02} For a prefix X that denotes a subtype or object:

X'Alignment

{AI95-00291-02} The value of this attribute is of type universal_integer, and nonnegative; zero means that the object is not necessarily aligned on a storage element boundary. If X'Alignment is not zero, then X is aligned on a storage unit boundary and X'Address is the Address of an object that is allocated under control of the implementation and X'Alignment is an integral multiple of X'Alignment, the Alignment of the object (that is, the Address modulo the Alignment is zero). The offset of a record component is a multiple of the Alignment of the component. For an object that is not allocated under control of the implementation (that is, one that is imported, that is allocated by a user-defined allocator, whose Address has been specified, or is designated by an access value returned by an instance of Unchecked_Conversion), the implementation may assume that the Address is an integral multiple of its Alignment. The implementation shall not assume a stricter alignment.

This paragraph was deleted.

{AI95-00291-02} The value of this attribute is of type universal_integer, and nonnegative; zero means that the object is not necessarily aligned on a storage element boundary.

Ramification: The Alignment is passed by an allocator to the Allocate operation; the implementation has to choose a value such that if the address returned by Allocate is aligned as requested, the generated code can correctly access the object.

The above mention of “modulo” is referring to the "mod" operator declared in System.Storage_Elements; if X \mod N = 0, then X is by definition aligned on an N-storage-element boundary.

{AI95-00291-02} Alignment may be specified for first subtypes and [stand-alone] objects via an attribute_definition_clause; the expression of such a clause shall be static, and its value nonnegative. If the Alignment of a subtype is specified, then the Alignment of an object of the subtype is at least as strict, unless the object's Alignment is also specified. The Alignment of an object created by an allocator is that of the designated subtype.

Aspect Description for Alignment (object): Alignment of an object.

This paragraph was deleted.

{AI95-00247-01} If an Alignment is specified for a composite subtype or object, this Alignment shall be equal to the least common multiple of any specified Alignments of the subcomponent subtypes, or an integer multiple thereof.

{AI95-00291-02} For every subtype S:

S'Alignment

{AI95-00291-02} The value of this attribute is of type universal_integer, and nonnegative.

{AI95-00051-02} {AI95-00291-02} For an object X of subtype S, if S'Alignment is not zero, then X'Alignment is a nonzero integral multiple of S'Alignment unless specified otherwise by a representation item.

{AI95-00291-02} Alignment may be specified for first subtypes via an attribute_definition_clause; the expression of such a clause shall be static, and its value nonnegative.
Program execution is erroneous if an Address clause is given that conflicts with the Alignment.

Ramiﬁcation: The user has to either give an Alignment clause also, or else know what Alignment the implementation will choose by default.

For if the Alignment is speciﬁed for an object that is not allocated under control of the implementation, execution is erroneous if the object is not aligned according to its Alignment.

Implementation Advice

For any tagged speciﬁc subtype \(S\), \(S'\text{Class} '\text{Alignment}\) should equal \(S'\text{Alignment}\).

Reason: A tagged object should never be less aligned than the alignment of the type of its view, so for a class-wide type \(T\text{Class}\), the alignment should be no greater than that of any type covered by \(T\text{Class}\). If the implementation only supports alignments that are required by the recommended level of support (and this is most likely), then the alignment of any covered type has to be the same or greater than that of \(T\) — which leaves the only reasonable value of \(T\text{Class}'\text{Alignment}\) being \(T'\text{Alignment}\). Thus we recommend this, but don't require it so that in the unlikely case that the implementation does support smaller alignments for covered types, it can select a smaller value for \(T'\text{Class}'\text{Alignment}\).

Implementation Advice: For any tagged speciﬁc subtype \(S\), \(S'\text{Class} '\text{Alignment}\) should equal \(S'\text{Alignment}\).

The recommended level of support for the Alignment attribute for subtypes is:

- An implementation should support an Alignment clause for a discrete type, fixed point type, record type, or array type, specifying an Alignment value that is zero or a power of two, specified Alignments that are factors and multiples of the number of storage elements per word, subject to the following:

- An implementation need not support an Alignment clause for a signed integer type specifying an Alignment greater than the largest Alignment value that is ever chosen by default by the implementation for any signed integer type. A corresponding limitation may be imposed for modular integer types, fixed point types, enumeration types, record types, and array types, specified Alignments for combinations of Sizes and Alignments that cannot be easily loaded and stored by available machine instructions.

- An implementation need not support a nonconforming Alignment clause which could enable the creation of an object of an elementary type which cannot be easily loaded and stored by available machine instructions, specified Alignments that are greater than the maximum Alignment the implementation ever returns by default.

- An implementation need not support an Alignment speciﬁed for a derived tagged type which is not a multiple of the Alignment of the parent type. An implementation need not support a nonconforming Alignment speciﬁed for a derived untagged by-reference type.

Ramiﬁcation: There is no recommendation to support any nonconforming Alignment clauses for types not mentioned above. Remember that 13.1 requires support for conﬁrming Alignment clauses for all types.

Implementation Note: An implementation that tries to support other alignments for derived tagged types will need to allow inherited subprograms to be passed objects that are less aligned than expected by the parent subprogram and type. This is unlikely to work if alignment has any effect on code selection. Similar issues arise for untagged derived types whose parameters are passed by reference.

The recommended level of support for the Alignment attribute for objects is:

- This paragraph was deleted.

- For stand-alone library-level objects of statically constrained subtypes, the implementation should support all Alignments supported by the target linker. For example, page alignment is likely to be supported for such objects, but not for subtypes.
• `{AI95-00291-02}` For other objects, an implementation should at least support the alignments supported for their subtype, subject to the following:

• `{AI95-00291-02}` An implementation need not support Alignments specified for objects of a by-reference type or for objects of types containing aliased subcomponents if the specified Alignment is not a multiple of the Alignment of the subtype of the object.

**Implementation Advice:** The recommended level of support for the Alignment attribute should be followed.

**NOTES**

4 Alignment is a subtype-specific attribute.

This paragraph was deleted. `{AI95-00247-01}` The Alignment of a composite object is always equal to the least common multiple of the Alignments of its components, or a multiple thereof.

This paragraph was deleted. **Discussion:** For default Alignments, this follows from the semantics of Alignment. For specified Alignments, it follows from a Legality Rule stated above.

6 `{AI05-0229-1}` `{AI05-0269-1}` A component_clause, Component_Size clause, or specifying the pragma Pack aspect as True can override a specified Alignment.

**Discussion:** Most objects are allocated by the implementation; for these, the implementation obeys the Alignment. The implementation is of course allowed to make an object more aligned than its Alignment requires — an object whose Alignment is 4 might just happen to land at an address that's a multiple of 4096. For formal parameters, the implementation might want to force an Alignment stricter than the parameter's subtype. For example, on some systems, it is customary to always align parameters to 4 storage elements.

Hence, one might initially assume that the implementation could evilly make all Alignments 1 by default, even though integers, say, are normally aligned on a 4-storage-element boundary. However, the implementation cannot get away with that — if the Alignment is 1, the generated code cannot assume an Alignment of 4, at least not for objects allocated outside the control of the implementation.

Of course implementations can assume anything they can prove, but typically an implementation will be unable to prove much about the alignment of, say, an imported object. Furthermore, the information about where an address “came from” can be lost to the compiler due to separate compilation.

{`AI95-00114-01`}` `{AI05-0229-1}` The Alignment of an object that is a component of a packed composite object will usually be 0, to indicate that the component is not necessarily aligned on a storage element boundary. For a subtype, an Alignment of 0 means that objects of the subtype are not normally aligned on a storage element boundary at all. For example, an implementation might choose to make Component Size be 16 for an array of Booleans, even when the pragma Pack aspect has not been specified for the array. In this case, Boolean'Alignment would be 0. (In the presence of tasking, this would in general be feasible only on a machine that had atomic test-bit and set-bit instructions.)

If the machine has no particular natural alignments, then all subtype Alignments will probably be 1 by default.

Specifying an Alignment of 0 in an attribute_definition_clause does not require the implementation to do anything (except return 0 when the Alignment is queried). However, it might be taken as advice on some implementations.

It is an error for an Address clause to disobey the object's Alignment. The error cannot be detected at compile time, in general, because the Address is not necessarily known at compile time (and is almost certainly not static). We do not require a run-time check, since efficiency seems paramount here, and Address clauses are treading on thin ice anyway. Hence, this misuse of Address clauses is just like any other misuse of Address clauses — it's erroneous.

A type extension can have a stricter Alignment than its parent. This can happen, for example, if the Alignment of the parent is 4, but the extension contains a component with Alignment 8. The Alignment of a class-wide type or object will have to be the maximum possible Alignment of any extension.

The recommended level of support for the Alignment attribute is intended to reflect a minimum useful set of capabilities. An implementation can assume that all Alignments are multiples of each other — 1, 2, 4, and 8 might be the only supported Alignments for subtypes. An Alignment of 3 or 6 is unlikely to be useful. For objects that can be allocated statically, we recommend that the implementation support larger Alignments, such as 4096. We do not recommend such large Alignments for subtypes, because the maximum subtype Alignment will also have to be used as the alignment of stack frames, heap objects, and class-wide objects. Similarly, we do not recommend such large Alignments for stack-allocated objects.

If the maximum default Alignment is 8 (say, Long_Float'Alignment = 8), then the implementation can refuse to accept stricter alignments for subtypes. This simplifies the generated code, since the compiler can align the stack and class-wide types to this maximum without a substantial waste of space (or time).

Note that the recommended level of support takes into account interactions between Size and Alignment. For example, on a 32-bit machine with 8-bit storage elements, where load and store instructions have to be aligned according to the
size of the thing being loaded or stored, the implementation might accept an Alignment of 1 if the Size is 8, but might reject an Alignment of 1 if the Size is 32. On a machine where unaligned loads and stores are merely inefficient (as opposed to causing hardware traps), we would expect an Alignment of 1 to be supported for any Size.

Wording Changes from Ada 83

The nonnegative part is missing from RM83 (for mod_clause, see alignment_clause, which are an obsolete version of Alignment clauses).

Static Semantics

For a prefix X that denotes an object:

X'Size Denotes the size in bits of the representation of the object. The value of this attribute is of the type universal_integer.

Ramification: Note that Size is in bits even if Machine_Radix is 10. Each decimal digit (and the sign) is presumably represented as some number of bits.

Size may be specified for [stand-alone] objects via an attribute_definition_clause; the expression of such a clause shall be static and its value nonnegative.

Aspect Description for Size (object): Size in bits of an object.

Implementation Advice

The size of an array object should not include its bounds.

The recommended level of support for the Size attribute of objects is the same as for subtypes (see below), except that only a confirming Size clause need be supported for an aliased elementary object.

• This paragraph was deleted. A Size clause should be supported for an object if the specified Size is at least as large as its subtype's Size, and corresponds to a size in storage elements that is a multiple of the object's Alignment (if the Alignment is nonzero).

Static Semantics

For every subtype S:

S'Size If S is definite, denotes the size [(in bits)] that the implementation would choose for the following objects of subtype S:

• A record component of subtype S when the record type is packed.

• The formal parameter of an instance of Unchecked_Conversion that converts from subtype S to some other subtype.

If S is indefinite, the meaning is implementation defined. The value of this attribute is of the type universal_integer. The Size of an object is at least as large as that of its subtype, unless the object's Size is determined by a Size clause, a component_clause, or a Component_Size clause. Size may be specified for first subtypes via an attribute_definition_clause; the expression of such a clause shall be static and its value nonnegative.

Implementation defined: The meaning of Size for indefinite subtypes.

Reason: The effects of specifying the Size of a subtype are:

• Unchecked_Conversion works in a predictable manner.

• A composite type cannot be packed so tightly as to override the specified Size of a component's subtype.

• Assuming the Implementation Advice is obeyed, if the specified Size allows independent addressability, then the Size of certain objects of the subtype should be equal to the subtype's Size. This applies to stand-alone objects and to components (unless a component_clause or a Component_Size clause applies).
A component_clause or a Component_Size clause can cause an object to be smaller than its subtype's specified size. The aspect pragma Pack cannot; if a component subtype's size is specified, this limits how tightly the composite object can be packed.

The Size of a class-wide (tagged) subtype is unspecified, because it's not clear what it should mean; it should certainly not depend on all of the descendants that happen to exist in a given program. Note that this cannot be detected at compile time, because in a generic unit, it is not necessarily known whether a given subtype is class-wide. It might raise an exception on some implementations.

**Ramification:** A Size clause for a numeric subtype need not affect the underlying numeric type. For example, if I say:

```ada
type S is range 1..2;
for S'Size use 64;
```

I am not guaranteed that $S\text{'Base'}\text{'}\text{Last} \geq 2^63–1$, nor that intermediate results will be represented in 64 bits.

**Reason:** There is no need to complicate implementations for this sort of thing, because the right way to affect the base range of a type is to use the normal way of declaring the base range:

```ada
type Big is range -2**63 .. 2**63 - 1;
subtype Small is Big range 1..1000;
```

**Ramification:** The Size of a large unconstrained subtype (e.g. String'Size) is likely to raise Constraint_Error, since it is a nonstatic expression of type universal_integer that might overflow the largest signed integer type. There is no requirement that the largest integer type be able to represent the size in bits of the largest possible object.

**Aspect Description for Size (subtype):** Size in bits of a subtype.

### Implementation Requirements

In an implementation, Boolean'Size shall be 1.

**Implementation Advice**

If the Size of a subtype is specified, and allows for efficient independent addressability (see 9.10) on the target architecture, then the Size of the following objects of the subtype should equal the Size of the subtype:

- Aliased objects (including components).
- Unaliased components, unless the Size of the component is determined by a component_clause or Component_Size clause.

**Implementation Advice:** If the Size of a subtype allows for efficient independent addressability, then the Size of most objects of the subtype should equal the Size of the subtype.

**Ramification:** Thus, on a typical 32-bit machine, “for S'Size use 32;” will guarantee that aliased objects of subtype S, and components whose subtype is S, will have Size = 32 (assuming the implementation chooses to obey this Implementation Advice). On the other hand, if one writes, “for S2'Size use 5;” then stand-alone objects of subtype S2 will typically have their Size rounded up to ensure independent addressability.

Note that “for S'Size use 32;” does not cause things like formal parameters to have Size = 32 — the implementation is allowed to make all parameters be at least 64 bits, for example.

Note that “for S2'Size use 5;” requires record components whose subtype is S2 to be exactly 5 bits if the record type is packed. The same is not true of array components; their Size may be rounded up to the nearest factor of the word size.

**Implementation Note:** {AI95-00051-02} On most machines, arrays don't contain gaps between elementary components; if the Component_Size is greater than the Size of the component subtype, the extra bits are generally considered part of each component, rather than gaps between components. On the other hand, a record might contain gaps between elementary components, depending on what sorts of loads, stores, and masking operations are generally done by the generated code.

**A Size clause on a composite subtype should not affect the internal layout of components.**

**Implementation Advice:** A Size clause on a composite subtype should not affect the internal layout of components.
The recommended level of support for the Size attribute of subtypes is:

- The Size (if not specified) of a static discrete or fixed point subtype should be the number of bits needed to represent each value belonging to the subtype using an unbiased representation, leaving space for a sign bit only if the subtype contains negative values. If such a subtype is a first subtype, then an implementation should support a specified Size for it that reflects this representation.

**Implementation Note:** This applies to static enumeration subtypes, using the internal codes used to represent the values.

For a two's-complement machine, this implies that for a static signed integer subtype S, if all values of S are in the range $0 .. 2^{n-1}$, or all values of S are in the range $-2^{n-1} .. 2^{n-1}$, for some $n$ less than or equal to the word size, then S'Size should be $\leq$ the smallest such $n$. For a one's-complement machine, it is the same except that in the second range, the lower bound $-2^n$ is replaced by $-2^{n-1}$.

If an integer subtype (whether signed or unsigned) contains no negative values, the Size should not include space for a sign bit.

Typically, the implementation will choose to make the Size of a subtype be exactly the smallest such $n$. However, it might, for example, choose a biased representation, in which case it could choose a smaller value.

**Reason:** \{AI05-0229-1\} On most machines, it is in general not a good idea to pack (parts of) multiple stand-alone objects into the same storage element, because (1) it usually doesn't save much space, and (2) it requires locking to prevent tasks from interfering with each other, since separate stand-alone objects are independently addressable. Therefore, if S'Size = 2 on a machine with 8-bit storage elements, the size of a stand-alone object of subtype S will probably not be 2. It might, for example, be 8, 16 or 32, depending on the availability and efficiency of various machine instructions. The same applies to components of composite types, unless Pack pragmas, Component_Size, or record layout is specified.

For an unconstrained discriminated object, if the implementation allocates the maximum possible size, then the Size attribute should return that maximum possible size.

**Ramification:** The Size of an object X is not usually the same as that of its subtype S. If X is a stand-alone object or a parameter, for example, most implementations will round X'Size up to a storage element boundary, or more, so X'Size might be greater than S'Size. On the other hand, X'Size cannot be less than S'Size, even if the implementation can prove, for example, that the range of values actually taken on by X during execution is smaller than the range of S.

For example, if S is a first integer subtype whose range is 0..3, S'Size will be probably be 2 bits, and components of packed composite types of this subtype will be 2 bits (assuming Storage_Unit is a multiple of 2), but stand-alone objects and parameters will probably not have a size of 2 bits; they might be rounded up to 32 bits, for example. On the other hand, Unchecked_Conversion will use the 2-bit size, even when converting a stand-alone object, as one would expect.

Another reason for making the Size of an object bigger than its subtype's Size is to support the run-time detection of uninitialized variables. The implementation might add an extra value to a discrete subtype that represents the uninitialized state, and check for this value on use. In some cases, the extra value will require an extra bit in the representation of the object. Such detection is not required by the language. If it is provided, the implementation has to be able to turn it off. For example, if the programmer gives a record_representation_clause or Component_Size clause that makes a component too small to allow the extra bit, then the implementation will not be able to perform the checking (not using this method, anyway).

The fact that the size of an object is not necessarily the same as its subtype can be confusing:

```
type Device_Register is range 0..2**8 - 1;
for Device_Register'Size use 8; -- Confusing!
My_Device : Device_Register;
for My_Device'Address use To_Address(16#FF00#);
```

The programmer might think that My_Device'Size is 8, and that My_Device'Address points at an 8-bit location. However, this is not true. In Ada 83 (and in Ada 95), My_Device'Size might well be 32, and My_Device'Address might well point at the high-order 8 bits of the 32-bit object, which are always all zero bits. If My_Device'Address is passed to an assembly language subprogram, based on the programmer's assumption, the program will not work properly.

**Reason:** It is not reasonable to require that an implementation allocate exactly 8 bits to all objects of subtype Device_Register. For example, in many run-time models, stand-alone objects and parameters are always aligned to a word boundary. Such run-time models are generally based on hardware considerations that are beyond the control of...
the implementer. (It is reasonable to require that an implementation allocate exactly 8 bits to all components of subtype Device_Register, if packed.)

**Ramification:** The correct way to write the above code is like this:

```ada
type Device_Register is range 0..2**8 - 1;
My_Device : Device_Register;
for My_Device'Size use 8;
for My_Device'Address use To_Address(16#FF00#);
```

If the implementation cannot accept 8-bit stand-alone objects, then this will be illegal. However, on a machine where an 8-bit device register exists, the implementation will probably be able to accept 8-bit stand-alone objects. Therefore, My_Device'Size will be 8, and My_Device'Address will point at those 8 bits, as desired.

If an object of subtype Device_Register is passed to a foreign language subprogram, it will be passed according to that subprogram's conventions. Most foreign language implementations have similar run-time model restrictions. For example, when passing to a C function, where the argument is of the C type char* (that is, pointer to char), the C compiler will generally expect a full word value, either on the stack, or in a register. It will not expect a single byte. Thus, Size clauses for subtypes really have nothing to do with passing parameters to foreign language subprograms.

- For a subtype implemented with levels of indirection, the Size should include the size of the pointers, but not the size of what they point at.

**Ramification:** For example, if a task object is represented as a pointer to some information (including a task stack), then the size of the object should be the size of the pointer. The Storage_Size, on the other hand, should include the size of the stack.

- **{AI95-00051-02}** An implementation should support a Size clause for a discrete type, fixed point type, record type, or array type, subject to the following:

  - **{AI95-00051-02}** An implementation need not support a Size clause for a signed integer type specifying a Size greater than that of the largest signed integer type supported by the implementation in the absence of a size clause (that is, when the size is chosen by default). A corresponding limitation may be imposed for modular integer types, fixed point types, enumeration types, record types, and array types.

**Discussion:** **{AI95-00051-02}** Note that the “corresponding limitation” for a record or array type implies that an implementation may impose some reasonable maximum size for records and arrays (e.g. 2**32 bits), which is an upper bound (“capacity” limit) on the size, whether chosen by default or by being specified by the user. The largest size supported for records need not be the same as the largest size supported for arrays.

**Ramification:** **{AI05-0155-1}** Only Size clauses with a size greater than or equal to the Size that would be chosen by default may be safely presumed to be supported on nonstatic elementary subtypes. Implementations may choose to support smaller sizes, but only if the Size allows any value of the subtype to be represented, for any possible value of the bounds.

- **{AI95-00291-02}** A nonconfirming size clause for the first subtype of a derived untagged by-reference type need not be supported.

**Implementation Advice:** The recommended level of support for the Size attribute should be followed.

**Ramification:** **{AI95-00291-02}** There is no recommendation to support any nonconfirming Size clauses for types not mentioned above. Remember that 13.1 requires support for confirming Size clauses for all types.

**NOTES**

7 Size is a subtype-specific attribute.

8 **{AI05-0229-1}** A component_clause or Component_Size clause can override a specified Size. **Aspect** A pragma **Pack** cannot.

**Inconsistencies With Ada 83**

**{AI95-00114-01}** We specify the meaning of Size in much more detail than Ada 83. This is not technically an inconsistency, but it is in practice, as most Ada 83 compilers use a different definition for Size than is required here. This should have been documented more explicitly during the Ada 9X process.

**Wording Changes from Ada 83**

The requirement for a nonnegative value in a Size clause was not in RM83, but it’s hard to see how it would make sense. For uniformity, we forbid negative sizes, rather than letting implementations define their meaning.
Static Semantics

For a prefix T that denotes a task object [(after any implicit dereference)]:

T'Storage_Size

{AI05-0229-1} Denotes the number of storage elements reserved for the task. The value of this attribute is of the type universal_integer. The Storage_Size includes the size of the task’s stack, if any. The language does not specify whether or not it includes other storage associated with the task (such as the “task control block” used by some implementations.) If the aspect pragma Storage_Size is specified for the type of the object given, the value of the Storage_Size attribute is at least the value determined by the aspect specified in the pragma.

Ramification: The value of this attribute is never negative, since it is impossible to “reserve” a negative number of storage elements.

If the implementation chooses to allocate an initial amount of storage, and then increase this as needed, the Storage_Size cannot include the additional amounts (assuming the allocation of the additional amounts can raise Storage_Error); this is inherent in the meaning of “reserved.”

The implementation is allowed to allocate different amounts of storage for different tasks of the same subtype.

Storage_Size is also defined for access subtypes — see 13.11.

{AI95-0229-1} [Aspect-a pragma] Storage_Size specifies the amount of storage to be reserved for the execution of a task.]

Paragraphs 62 through 65 were moved to Annex J, “Obsolescent Features”.

Syntax

{AI05-0229-1} The form of a pragma Storage_Size is as follows:

pragma Storage_Size(expression);

{AI05-0229-1} A pragma Storage_Size is allowed only immediately within a task_definition.

Name Resolution Rules

{AI05-0229-1} The expression of a pragma Storage_Size is expected to be of any integer type.

Static Semantics

{AI05-0229-1} {AI05-0269-1} For a task_type (including the anonymous type of a single_task_declaration), the following language-defined representation aspect may be specified:

Storage_Size

The Storage_Size aspect is an expression, which shall be of any integer type.

To be honest: This definition somewhat conflicts with the "automatic" one for the obsolescent attribute Storage_Size (which can be specified). The only difference is where the given expression is evaluated. We intend for the above definition to supersede that "automatic" definition for this attribute.

Ramification: Note that the value of the Storage_Size aspect is an expression; it is not the value of an expression. The expression is evaluated for each object of the type (see below).

Aspect Description for Storage_Size (task): Size in storage elements reserved for a task type or single task object.

Legality Rules

{AI05-0229-1} The Storage_Size aspect shall not be specified for a task interface type.

Dynamic Semantics

When a task object is created, the expression (if any) associated with the Storage_Size aspect of its type A pragma Storage_Size is elaborated when an object of the type defined by the immediately-enclosing task_definition is created. For the elaboration of a pragma Storage_Size, the
expression is evaluated; the Storage_Size attribute of the newly created task object is at least the value of the expression.

**Ramification:** The implementation is allowed to round up a specified Storage_Size amount. For example, if the implementation always allocates in chunks of 4096 bytes, the number 200 might be rounded up to 4096. Also, if the user specifies a negative number, the implementation has to normalize this to 0, or perhaps to a positive number.

> {AI05-0229-1} If the Storage_Size aspect is not specified for the type of the task object, the value of the Storage_Size attribute is unspecified.

At the point of task object creation, or upon task activation, Storage_Error is raised if there is insufficient free storage to accommodate the requested Storage_Size.

**Static Semantics**

For a prefix X that denotes an array subtype or array object [(after any implicit dereference)]:

X'Component_Size

Denotes the size in bits of components of the type of X. The value of this attribute is of type `universal_integer`.

Component_Size may be specified for array types via an `attribute_definition_clause`; the expression of such a clause shall be static, and its value nonnegative.

**Implementation Note:** The intent is that the value of X'Component_Size is always nonnegative. If the array is stored “backwards” in memory (which might be caused by an implementation-defined pragma), X'Component_Size is still positive.

**Ramification:** For an array object A, A'Component_Size = A(I)'Size for any index I.

**Aspect Description for Component_Size:** Size in bits of a component of an array type.

**Implementation Advice**

The recommended level of support for the Component_Size attribute is:

- An implementation need not support specified Component_Sizes that are less than the Size of the component subtype.
- \{AI05-0229-1\} An implementation should support specified Component_Sizes that are factors and multiples of the word size. For such Component_Sizes, the array should contain no gaps between components. For other Component_Sizes (if supported), the array should contain no gaps between components when Pack is also specified; the implementation should forbid this combination in cases where it cannot support a no-gaps representation.

> {AI05-0229-1} For example, if Storage_Unit = 8, and Word_Size = 32, then the user is allowed to specify a Component_Size of 1, 2, 4, 8, 16, and 32, with no gaps. In addition, n*32 is allowed for positive integers n, again with no gaps. If the implementation accepts Component_Size = 3, then it might allocate 10 components per word, with a 2-bit gap at the end of each word (unless Pack is also specified), or it might not have any internal gaps at all. (There can be gaps at either end of the array.)

**Implementation Advice:** The recommended level of support for the Component_Size attribute should be followed.

\{AI05-0191-1\} For a prefix X that denotes an object:

**X'Has_Same_Storage**

\{AI05-0191-1\} X'Has_Same_Storage denotes a function with the following specification:

```
function X'Has_Same_Storage (Arg : any_type) return Boolean
```

\{AI05-0191-1\} \{AI05-0264-1\} The actual parameter shall be a name that denotes an object. The object denoted by the actual parameter can be of any type. This function evaluates the names of the objects involved and returns True if the representation of the object denoted by
the actual parameter occupies exactly the same bits as the representation of the object denoted by X; otherwise, it returns False.

Discussion: Has_Same_Storage means that, if the representation is contiguous, the objects sit at the same address and occupy the same length of memory.

{AI05-0191-1} For a prefix X that denotes an object:

X'Overlaps_Storage

{AI05-0191-1} X'Overlaps_Storage denotes a function with the following specification:

function X'Overlaps_Storage (Arg : any_type) return Boolean

{AI05-0191-1} {AI05-0264-1} The actual parameter shall be a name that denotes an object. The object denoted by the actual parameter can be of any type. This function evaluates the names of the objects involved and returns True if the representation of the object denoted by the actual parameter shares at least one bit with the representation of the object denoted by X; otherwise, it returns False.

NOTES

9 {AI05-0191-1} X'Has_Same_Storage(Y) implies X'Overlaps_Storage(Y).
10 {AI05-0191-1} X'Has_Same_Storage(Y) and X'Overlaps_Storage(Y) are not considered to be reads of X and Y.

Static Semantics

{8652/0009} {AI95-00137-01} {AI05-0183-1} The following type-related operational attribute is defined: External_Tag.

{8652/0009} {AI95-00137-01} For every subtype S of a tagged type T (specific or class-wide), the following attribute is defined:

S'External_Tag

{8652/0040} {AI95-00108-01} {AI05-0092-1} S'External_Tag denotes an external string representation for S'Tag; it is of the predefined type String. External_Tag may be specified for a specific tagged type via an attribute_definition_clause; the expression of such a clause shall be static. The default external tag representation is implementation defined. See 3.9.2 and 13.13.2. The value of External_Tag is never inherited; the default value is always used unless a new value is directly specified for a type.

Implementation defined: The default external representation for a type tag.

Aspect Description for External_Tag: Unique identifier for a tagged type in streams.

Dynamic Semantics

{AI05-0113-1} If a user-specified external tag S'External_Tag is the same as T'External_Tag for some other tagged type declared by a different declaration in the partition, Program_Error is raised by the elaboration of the attribute_definition_clause.

Ramification: This rule does not depend on the visibility of the other tagged type, but it does depend on the existence of the other tagged type. The other tagged type could have the default external tag or a user-specified external tag.
